The 1st day of January last I was consulted by Miss F., age 23, who had had a contralto voice of large power, which she had employed constantly for several years, and had finally, after a prolonged concert tour with a well-known orchestra, entirely broken down. Her cords were dark red, with a slight nodule in the middle of either band. She complained of great pain in producing her notes, and her medium register had no power in it whatsoever. She had been told by two of the best authorities on the throat that she must not sing a note for a year, and must have her cords painted with astringent solutions and tone up her general health. Upon testing her voice, I remarked an extremely breathy tone and clavicular respiration. In accordance with the principles which I have attempted to demonstrate, I forbade her speaking a single word for a week, but placed her at once upon the so-called "inferior costal respiration," maintaining a high chest, and giving her direction to take a medium "C" with the chin almost resting upon the clavicle singing the word "ma" for five minutes of each hour of the day, the tone first to be focused in the face with the mouth closed and the attack to break upon the lips as much as possible on opening the mouth. At the end of seven days the cords, instead of presenting an elliptical appearance, were straight, and the nodule was so far rotated upward on either cord that it did not touch the nodule of the opposite side in the emission of tone. At the end of the week this young lady, who considered her voice hopelessly destroyed, having acquired a new method of respiration, sang in a concert. She has since sung regularly in church, in many oratorios during the winter, and is at present singing three times a week in grand opera, learning new rôles continually, apparently perfectly restored. She tells me her voice is far more powerful than she had ever dreamed of.

*Case 2.*—Miss P. H. consulted me on March 2, in great distress. She was obliged to sing in a comic opera on that evening or close the theater. Examination showed inflamed and bulged cords, with great hoarseness in the speaking voice; middle register impossible, but the high notes obtained with great effort. I sent her at once to my assistant, who gave her exercises to maintain tension, and at the end of an hour's work with tension exercises and inferior costal breathing the cords responded and she sang with ease.

*Case 3.*—Miss H. B. consulted me in May, having lost her position as prima donna by reason of loss of voice. Had been constantly treated. Her cords showed the nodules of attrition, the result of the employment of the *coup de glotte* and faulty respiration. In this case a week's work caused the nodules to disappear. She adopted a proper laryngeal poise and again assumed the leading rôle.

*Observation.*—In this class of cases rest causes a relaxation of the cords and singing becomes impossible for some time, whereas constant work with tension of the cords and nonapproximation of the same gives immediate relief.

*Case 4.*—Fraulein K. consulted me in the spring. Her cords appeared swollen and the membrane was injured but not hyperæmic. Had been obliged to cancel her engagements and return to New York for treatment. I recognized the familiar picture and sent her to my assistant, who cured her in a week without other treatment than the establishment of a proper laryngeal poise.

With many cases like these which I might cite, may I not be excused in calling attention to what I consider the most important ground principle of the singer's art, namely, the proper employment of the muscles of respiration, the poise given the cords, and the proper use of the intrinsic muscles of the larynx, not forgetting the bringing into play of the accessory resonance cavities of the face, which lend so much color to the tone, removing entirely from the cords the deleterious effects of an improper initial attack?

To rehearse briefly the deductions which I have attempted to draw from my argument, I maintain that the best method of respiration is the inferior costal or diaphragmatic, faithfully maintaining the elevation of the upper ribs without raising the shoulders. Next in importance is the depression of the thyroid cartilage, brought about through the agency of the crico-thyroid muscle, and the pulling down of the trachea by increasing the capacity of the upper lobes of the lung. Be careful that the initial attack is removed entirely from the cords. Lower the uvula and soft palate that the sound waves may obtain their inter-current vibrations or harmonics by partly passing into the nasal cavities from behind. Let us not fall into the error that the roof of the mouth alone is the sounding board of the singing voice, for without that added richness and timbre to be given by calling into play nature's resonance pipes, the nose and its accessory cavities, we may sing, but the singing is at the expense of the cords and the life of the voice is necessarily shortened. If I have said enough to arouse a new interest in what I consider a most necessary accessory to laryngology I shall feel amply repaid for my endeavors to set the theme before you in a clear and comprehensive manner.

---

#### DISCUSSION.

Dr. JOHN N. MACKENZIE, Baltimore. I have nothing to add to the admirable paper of Dr. Curtis, except to second what he says concerning the vast importance of vocal gymnastic exercises in the treatment of affections such as he describes. In his office last May I saw a very striking illustration of its power for good in the person of the first case he has reported. I think this whole question of vocal gymnastics is going to play a very important rôle hereafter in the treatment of minor affections of the vocal apparatus.

Dr. H. HOLBROOK CURTIS, New York City. I wish to dwell upon the importance of this question and the interest it should arouse, because, as Dr. McKenzie has said, it is in the hyperæmic conditions where we encounter chronic affections of the vocal cords from lack of tension, the cords with nodules in the center, where the person is hoarse in the morning and hoarse after singing. It is in those cases that gymnastic exercises of the intrinsic muscles do so much good. I took a choir singer in New York who had lost her voice from a papilloma on the cord. After scraping the cord I put her on these exercises, and she recovered her voice with a brilliancy it had never possessed before. She has since adopted this system of teaching for a livelihood, and does nothing else except give these exercises to singers, thereby making a very comfortable income. Professional people who go to her recommend her to others. This has shown me that we have been groping around for a long time in this condition of the cords, trying to cure them by electricity and in various ways, whereas the true principle of treatment should be the cultivation of the proper poise of the larynx, and practicing mild tension

of the cords, in order that they do not touch when making the initial tones. By taking these exercises constantly, you pull a cord from a bulging condition into normal straightness without the loss of a day's work, and this is important to singers and actors. You can take a man with chronic laryngitis, who has perhaps been drinking a good deal, and in a couple of days he may be put in good condition, whereas by the old method it would take a couple of weeks.

#### ASPERGILLUS MYCOSIS OF THE MAXILLARY ANTRUM.

By Dr. JOHN N. MACKENZIE, of Baltimore, Md.

I was not aware until I arrived in Washington that a paper was expected of me. This fact, together with the intense heat, compels me to read a paper which I have not yet written. In the early part of last November I presented a case before the Johns Hopkins Medical Society which will furnish the text for my remarks to-day.

I wish to call your attention to a new disease of the antrum. As far as I can find from consulting literature the condition was never described until I presented this case, which was that of a young lady who, in 1883, consulted Dr. Theobald, of Baltimore, on account of pain in the right ear, which he said was as well marked a case of pure otalgia as one would ever see. This was the usual symptom that would bring her to see him from time to time. Often there was nothing wrong to be seen in the ear, but at other times there would be a swelling of the outer third of the meatus and tenderness on pressure. March 4, 1889, a threatening furuncle appeared in the auditory canal; in October, 1887, an abscess of the lobe of the ear, which was opened by Dr. Theobald. There never was at any time aspergillus in the ear, nor even a condition which would suggest a probability of its presence. Dr. Theobald first noticed a swelling on the right side of the face January 7, 1889, and a week later recognized the presence of a disease of the antrum, she having had a discharge of pus from the nose with relief of pain and diminution of swelling of the cheek in the meantime. February 27, 1891, he noticed some swelling over the root of the nose, with pain over the right eye, and he feared there was trouble beginning in the frontal sinuses. These symptoms disappeared later. Dr. Theobald was disposed to think that the disease in the antrum had something to do with the ear symptom, and perhaps was the chief cause of the otalgia which she had from time to time. About two years ago her dentist brought her to Baltimore in consultation with Dr. James H. Harris, and from the history which Dr. Harris got of her antral trouble he seemed to think that the trouble was due in the first instance to caries of a molar tooth possibly originating as a variety of periodontal inflammation, with subsequent antral trouble. The antrum was opened at that time (the second molar tooth was extracted, and the floor perforated by a large drill) and an immense amount of pus washed out with a syringe. She was seen subsequently by several general surgeons who insisted upon scraping out the antrum. She was a little afraid of the operation and declined it. So things have been going on for the past two years, the antrum being syringed out daily with various alterative, astringent, and antiseptic solutions. The only drug which seemed to give her any relief at all was nitrate of silver in strong solution. This would stop the discharge for a week or two, and then it would become as bad as ever.

One of the chief points of interest in this case was the passage from the antrum of large quantities of false membrane. You all know that Zuckerkandl, who, above all other German investigators, has thrown light upon antral troubles, says that the structure of the antral mucous membrane is such as to preclude the formation of false membrane; therefore he denies the possibility of any diphtheritic membrane forming in the antrum. This case, of course, overthrows this postulate of Zucker-

kandl's. The membrane was a well-formed false membrane and it was passed from the antrum in large quantities during weeks and weeks. I obtained some of the membrane and sent it to Dr. Flexner, assistant pathologist at the Johns Hopkins University. Dr. Flexner has all my preparations, and as he is in Europe now I am not able to show you the beautiful work he has done, but shall have to content myself with a description of the microscopical appearance.

The membrane consists of three layers. The first layer consists of a mass of round cells with some loose epithelium of the mucous membrane of the sinus. The second layer is apparently one of pure necrosis, which does not stain. Upon this layer rests a mass of the so-called aspergilli. Dr. Flexner inclines to the belief that it is the *aspergillus fumigatus*. The *aspergillus* sends its spores in two directions, off from the free surface and down into the deep layers.

The subject of *aspergillus* infection is receiving some attention at the present day. Apparently very little is known about it. Of course we are all familiar with the fact that the *aspergillus* frequently infects the auditory canal and is also found on the cornea. The variety that is found in the auditory canal and on the cornea is the *aspergillus niger*, which is the least infectious of the three main varieties of *aspergillus*; these are the *niger*, the *flavus*, and the *fumigatus*. There seems to be more danger connected with the *fumigatus* than with either of its brethren, the *niger* or the *flavus*. *Aspergillus* infection is quite common among some birds, for example, the dove and various other smaller birds. Flüge states that it is found quite commonly in zoological gardens among the animals, *aspergillus fumigatus* being the variety most often met with; it is inhaled and sets up a pneumonia, which differs from ordinary pneumonia in that it proceeds rapidly to necrosis of the lung tissue.

*Aspergilli* seem to flourish best on moist soil and on mucous membranes where the epithelium has become moistened and loosened; they are sometimes produced by injections of oily matter. I have very carefully gone into the history of this case and find no reason to believe that at any period of her trouble was fluid injected into the antrum which might have brought the *aspergillus* spores. They may have lain there dormant for months. According to the natural history of these parasites, they may remain on a membrane a considerable time before evidence of their existence is forthcoming. We rarely see parasites in the nasal passages or the accessory cavities in our climate; they are found in southern climates, as you know. As I have not the sections here to show you, I will read a short extract from Dr. Flexner's report:

The thickness of the separate layers did not exceed 3 to 4 mm. and the membrane was found to be very friable. Sections showed on microscopical examination several layers. The undermost layer was composed of polynuclear leucocytes. This varied in thickness in different parts and formed about one-third of the entire thickness of the false membrane. A few cells of a different type, larger, with more protoplasm and vesicular nuclei, being sometimes flat and scale-like, and again narrow, elongated, and columnar, were present in the layer of leucocytic aggregation. These epithelial cells presented evidences of degeneration in the staining properties of the protoplasm as well as in the shriveled appearance and diffuse staining of the nuclei. Above the layer of leucocytes an indefinite substance was found, composed of granules and fiber-like processes which stained poorly in hæmatoxylin and eosine. But in the specimens stained in Weigert's fibrin stain this layer was seen to be felted and composed in large part of mycelia of a fungus. The uppermost layer of the membrane is composed of branches from the mycelia below, bearing on their summits the fruit-bearing heads. The fungus was recognized as belonging to the *aspergilli*, and Dr. Lotzy, who examined the specimen, finds it to be the *aspergillus fumigatus*.

This subject which I have brought before you is a twice-told tale; I have presented it to the Johns Hopkins Society and the American Laryngological Association. As far as I can make out, this is an entirely new disease added to our list of antral affections.

## DISCUSSION.

Dr. MERRICK. Dr. Mackenzie has certainly presented a very interesting paper, but I should like to know what means of treatment were adopted and with what degree of success.

Dr. MACKENZIE. I only saw the case twice in consultation. The patient lives at a distance from Baltimore, and I have not yet received the final report of her attending physician. All sorts of things were used—nitrate of silver, zinc, iron, iodoform packing, and almost everything you could think of. The only thing that seemed to do any good, and that only temporarily, was the application of a strong solution of nitrate of silver to the antral cavity. Of course the only way to get rid of the trouble is to scrape the disease out of the antrum, but that she will not have done.

## HYSTERICAL APHONIA AND DEAFNESS.

By E. FLETCHER INGALS, A. M., M. D., of Chicago, Ill.

Hysterical aphonia is so common that little of interest can be said concerning it, but hysterical deafness is comparatively rare. I find reports of a few cases, but have never met with it myself, excepting in a single instance, a brief history of which I think will be of interest to this congress. The case is that of Miss P. A. J., aged 23 years, and a teacher by profession, who recently came to America from Ceylon. She had been annoyed for three years by weakness of the voice, and occasionally by complete aphonia, and had been slightly deaf. About two years ago, while making an ocean voyage, she was greatly alarmed by a rat springing upon her. Immediately thereafter she lost the sense of hearing, and since that time has been so deaf that she could not hear ordinary conversation, and could only understand when addressed in very loud tones with the person's lips close to her ear.

When she came to see me, in the early part of July, 1893, she was still extremely nervous, and complained of dryness in the throat, inability to speak excepting in a whisper, and deafness so great as to require shouting to enable her to hear. Her general health was good; there was no history of predisposition to disease; pulse 100, temperature 100°; no cough or expectoration; appetite fair, and digestion normal. The hearing, tested by an ordinary watch, showed that no sounds whatever were appreciated even when the watch was placed in contact with the ear or temporal bones. The left membrana tympani was considerably thickened; the right normal. There was no congestion of the larynx, and the cords were well approximated on attempted phonation; but this condition could not be maintained. She talked only in a whisper, but upon directing her to sound the letter "a," while examining her larynx, I found that she could easily produce loud sounds. The excitation of pulse and elevation of temperature were temporary. I applied a mild astringent spray to the larynx and a solution of menthol, 5 grains to the ounce of liquid albolene, to the Eustachian tubes, through the naso-pharynx, the application being made by a long-tipped Davidson's No. 59 atomizer, which was introduced back of the palate, the spray being driven in with an air pressure of 15 pounds, while the nostrils were tightly closed. She was given internally berberine muriate, 1 grain; extract of valerian, 2 grains, and strychnine sulphate in doses of one-twentieth of a grain, which I proposed to increase rapidly to one-tenth or even one-eighth of a grain. Three days later it was noted that she felt something better, stating there was a "softening" in the ears, and seven days after the first treatment her friends stated that she occasionally spoke aloud, though in a low voice, and that her hearing was decidedly improved. At this time

the dose of strychnine was increased to one-sixteenth of a grain, and three days later to one-twelfth of a grain, four times daily. Four days later it was increased one-tenth of a grain and combined with extract of valerian, 2 grains, and asafoetida, 3 grains, which she took for five days, when (nineteen days after the beginning) one-eighth of a grain of strychnine was ordered in the same combination. This she took four times before the toxic effects of the strychnine became manifest. It was continued, notwithstanding the spasms, for two days subsequently and then reduced to two doses per day for five days. The convulsive movements continued to occur at evening for a couple of days after diminution of the quantity of strychnine, and then disappeared. The following day the friends reported that her hearing was greatly improved. Two days later (one month after beginning treatment) her hearing was apparently much improved for ordinary conversation. She talked aloud much of the time, but occasionally lapsed into whispers. The dose of strychnine was again increased to one-tenth of a grain four times a day and given in combination with extract of valerian, 3 grains. The strychnine will be continued in sufficient doses to cause slight twitching of the muscles, electricity will be used, and at the same time some simple topical application containing a small amount of menthol, for its physical effect. The case is still under treatment.

---

#### DISCUSSION.

Dr. S. K. MERRICK, Baltimore. This case is certainly one of great interest, the like of which I have never seen. I have, of course, had cases of hysterical aphonia. I would like to ask whether Dr. Ingals considers this a case of uncomplicated hysterical deafness? I understood him to say there was some reddening of the membrane. It occurs to me the length of time in securing results might throw some doubt upon the question of its being entirely of hysterical origin. Within the last six months a young girl came to my office, accompanied by her sister as spokeswoman. She was unable to speak at all except in a whisper. She said she felt perfectly well otherwise; there was no history of hysteria, nothing to indicate that it was a case of hysterical aphonia, yet on closer examination I found the larynx perfectly normal. There is one suggestive point in Dr. Ingals's paper—one remedy I had never used until I used it in this case. I was satisfied of the diagnosis and assured the girl that her voice would be instantaneously cured—it had been three days since she had spoken. It occurred to me menthol would be an excellent thing to use. She took three inhalations with 20 pounds pressure, and immediately spoke, talking as well as anybody, and she has never had any subsequent trouble. I think we usually get good results very quickly in these cases if there is no other element standing in a causative relation.

Dr. H. HOLBROOK CURTIS, New York City. I have had one case of hysterical aphonia associated with deafness, but it never occurred to me until I heard this paper that there was an association between the hysteria and the deafness. The cure was made in the following way: The lady went out sailing, and in going ashore on a small boat stepped on the rail and went down between the boat and the yacht. She screamed for help, and from that moment she spoke; and, as I remember now, her deafness is much better; in fact, I have not heard her allude to it since. In all the cases I have seen of aphonia which might be considered hysterical, I have observed that there was a thickening of the ventricular bands.

Dr. JAMES E. LOGAN, Kansas City, Mo. For the last two weeks I have been attending a case, not of hysterical deafness, but of hysterical aphonia, which was pronounced, but did not recover as I expected it to, and I simply state the case in order that I may get some information in regard it. I have made a close examination of the case. I can see the condition of the larynx perfectly, and the only thing

I can find there is a considerable thickening of the ventricular bands, but no inflammation. She has spoken in a whisper for six months, but when I ask her to sound the letter "a," or "ah," she speaks it distinctly, and she coughs distinctly. She was sent to me by physicians in Indian Territory with what they thought was tubercular laryngitis. There is no evidence of bacilli, no enlargement except of these bands. I can look down the trachea and can find no evidence of ulceration. I saw a little granulation in the anterior commissure, but with an application of chromic acid it passed away; but it was above the vocal cords and could have given no trouble in that respect. I can not bring about a relief or cure of her condition. She is now at my home, and I am anxious to find something that will relieve her.

This question of hysterical deafness is certainly very interesting. I would like to know the condition of the patient's ear previous to this deafness coming on, as it seems Dr. Ingals found considerable thickening of the left membrane; in that event she certainly could not hear very well out of the left ear, but the right ear being normal makes up for the deficiency, and being so totally deaf I should think was due to the hysterical condition. This question of hysterical aphonia is interesting to me, because I have had several cases and have not been able to relieve them as soon as I thought they ought to be relieved. The patient I speak of is a little Indian woman of nervous temperament, with great vitality; she makes every effort to speak, but says it hurts her.

Dr. MACKENZIE. I think we cure these cases more by psychical impression than anything else.

Dr. LOGAN. I would like to say that I tried that on my last case; I set a day for operation, and told the lady when the operation was performed I would have her speaking. I went down with a long forceps and played around in the larynx for awhile. She was very much wrought up about it. I knew I was not accomplishing anything, for I had nothing to accomplish. It made no such impression. When I have her go through the scale the ventricular bands do not move at all, but the cords act perfectly; the bands do not seem to obstruct the action of the cords at all. But the moment she loses sight of my constant effort to have her speak audibly the sound is but little above a whisper, and the ventricular bands approximate within two-thirds of their surface.

Dr. PRICE-BROWN, Toronto. I would like to say a word in regard to the treatment of Dr. Ingals's cases. As I understand it, he places much more stress upon the importance of strychnine than menthol, but the point I wish to make is the possibility of the cumulative effect in giving strychnine in increasing doses for such a long period. I should be afraid to give it in that way and still have the spasmodic effect of the strychnine. I would like to have the experience of others on that point, because we might be inclined to give strychnine in increasing doses in neurotic cases, and it is a question with me whether it would be safe to do so. I think in this case the strychnine produced the cure and that the menthol did not have much to do with it.

Dr. E. FLETCHER INGALS, Chicago. The question asked as to whether the case I reported was entirely hysterical I think was answered in the paper. There had been slight deafness before the fright; there was some thickening of the drum membrane. The suggestion that the length of time required to obtain relief threw some doubt upon the hysterical nature of the affection, reminds me that hysterical patients are not always cured promptly. I recall one case of hysterical aphonia that I treated for a year and a half before I succeeded in effecting a cure. She had been aphonic for five years before I saw her. I have seen many patients in whom the hysterical symptoms have not disappeared promptly that were cured by a few weeks of treatment. I suggested placing reliance upon the sulphate of strychnine, which I use, and I am glad to speak of it again, because it is, to my mind, the most important remedy we possess in the treatment of hysterical aphonia, and it was

for that reason I gave it in hysterical deafness. It may be given with safety and benefit for a long time and in large quantities. I have given to various patients one-eighth of a grain four times a day for weeks, though I begin with about one-twenty-fourth of a grain and reach the large dose gradually. I do not expect to obtain any decided benefit from it until I get the muscles to twitching. I recently saw a patient who had been under my care two years ago for laryngitis, which appeared to be tubercular. After considerable improvement she went to her home in Iowa, and when she returned recently her larynx was practically normal, but she could not talk aloud, the aphonia being of only about two weeks' standing. I placed her upon the sulphate of strychnine, running up the dose to one-tenth of a grain four times a day before I obtained clonic contraction of the muscles. A day or two afterwards she had two or three convulsions, which were quite frightful to herself and friends, but which had the desired effect of restoring her voice. As to the danger in continued use of this drug, we may get what is called the cumulative effect, but I think there is no harm from it, so long as we increase the dose gradually and watch the patient. As soon as convulsive movements occur the dose is diminished or the remedy temporarily suspended. When a patient has once been brought fully under its influence we usually find that two-thirds of the dose that had been taken previously can not be borne afterwards. My rule is to gradually increase the dose until I get the toxic effects of the drug and then reduce the amount until it causes only slight twitching at times, and to continue this, if necessary, for three or four weeks. This remedy will accomplish more for the cure of hysterical aphonia than any other drug or method I have ever used. A question was raised regarding phonatory approximation of the ventricular bands. I am sure that they are closely approximated in some cases, for I well remember one in which it was impossible to see the tone cords during phonation because the ventricular bands always closed first.

### ELECTRICAL ILLUMINATOR.

By Dr. D. BRYSON DELAVAN, of New York City.

I have been experimenting for several years with the view of evolving a convenient and practical electrical illuminator, and have here the product of that experimentation. It has been in use for a year and a half, and with success. The disadvantages of illumination by gas of course are obvious. The fact that gas evolves a large amount of heat and a certain amount of smoke and deleterious vapor, and that we are obliged to stay in our offices many hours each day and may thus suffer directly from its use, is a matter of common observation. It is desirable that electric light should be utilized, not only for the sake of health, but for the reason that in it we have a light that is manageable, the color of which is stable and uniform, and which in every respect is vastly more convenient than gas. The ordinary incandescent lamp with a single horseshoe loop, the ordinary loop filament, can not be adapted to our purpose by means of any mechanism I have been able to find. The objection to it is that the shadow or form of the loop filament is always in sight, no matter through how many series of reflectors it may be thrown. The reflection of the incandescent filament is dazzling to the eye as one looks into the laryngoscopic mirror, while the region in its neighborhood is in shadow. In order to adapt the light to our purposes it was necessary to make a new lamp and do away with the ordinary loop filaments. Many varieties of lamp were tried, the object of all being to concentrate the light as nearly as possible at one point, instead of distributing it through a long loop. The lamp finally selected is furnished with a single filament which has four convolutions,

the object being to collect a strong, uniform mass of light at one point. That mass of light, when the lamp is held horizontally, is distributed with fair uniformity in the lamp itself; not sufficiently so, however, to serve our purpose. In other words, if this light were to be thrown directly on the head mirror and reflected into the pharynx of a patient, it would be dazzling and uneven. In order to overcome this we throw between the light and the head mirror a small plano-convex lens, such as is used in the ordinary Mackenzie condenser. This materially distributes the light, takes away its dazzling properties, and causes it to be distributed pretty evenly over the surface of the reflector. In order to make the distribution of the rays perfect I used for some time a lamp with a ground-glass shade. This was expensive, however, about 30 per cent of the illuminating power being lost. Instead of this a plain lamp was substituted and the surface of the lens itself was ground. By this means a sufficient distribution of light is obtained to throw it evenly over the surface of the head mirror and to secure a perfect illumination from the latter. In short, a 40-candle-power Edison lamp with a peculiar filament is set horizontally in a hollow cylinder, the latter being merely a case to hold the lamp. The plano-convex lens is fastened to one end of the cylinder and the electric plug with the lamp to the other end. The current derived from the street is regulated by means of a common shut-off, the whole is mounted upon a suitable stand, and the apparatus is complete. I have used it in one form or another for the last two years, the last year and a half in the shape it is herewith presented, for all my examinations, and since using this particular 4-spiral filament lamp have had no difficulty whatever. One objection to the lamps of other varieties formerly used was that they quickly burned out. I have two lamps now which have been in constant use for over six months and which seem as good as ever, the lights having been in use several hours every day. The apparatus is made by the Edison Manufacturing Company, No. 110 East Twenty-third street, New York.

Dr. INGALS. I would ask whether the rays of light leaving the apparatus are divergent, parallel, or convergent?

Dr. DELAVAN. They are convergent.

---

## REPORT UPON CASES OF TUBERCULAR LARYNGITIS TREATED IN COLORADO SPRINGS.

By S. EDWIN SOLLY, M. D.

I desire to report to you the general features and results of 45 cases of laryngeal tuberculosis treated by me in Colorado Springs, which place stands at an altitude of 6,000 feet. I have gathered together 250 cases of pulmonary tuberculosis, and the 45 cases are all of these in which there was unmistakable evidence of laryngeal tuberculosis. These 250 cases are not all the cases of pulmonary or laryngeal tuberculosis treated by me during the eighteen years of practice in this region, but are all that I had opportunity to follow out, and watch, and obtain such knowledge of as would enable me to speak definitely of their progress and results, and in order to allow a reasonable time to have elapsed before reporting I have taken no cases that were seen for the first time in the past two years and only those that were treated by me personally. As far as these conditions allowed the cases were taken as they happened to come and may be considered a fair sample of what the total of the cases would probably show if all the records had been complete, and this opinion as regards the whole 250 cases is confirmed by their similarity in quality and results to the cases reported by other observers treated in this and similar altitudes. I could obtain no reports of laryngeal cases alone to compare them with; as to results, reports of cures of laryngeal tuberculosis after treatment are reported,

but none that I knew of that have been any length of time under observation. It will be observed that in the duration of the disease there is a relative likeness to reports of cases in low climates as given by others and also a close resemblance in the percentage of laryngeal cases among the whole number of those with pulmonary tuberculosis, while the percentage in whom ulceration was found is close to that from Schroetter's autopsies though smaller than Willigk's or Mackenzie's. It is therefore, I believe, fair to infer that the cases are of an average quality, and this is shown by their resemblance to the reports of pulmonary tuberculosis treated at an altitude made by other observers. While these results could not have been obtained without treatment, yet in many of the cases similar treatment previously used in low climates failed of any such results.

*Frequency of laryngeal tuberculosis among cases of phthisis.*

Twenty-five of the laryngeal cases showed clear signs of tubercular infiltration, which had not, however, proceeded to ulceration at the time of the first examination, though some of them did subsequently, while 20 cases had ulceration as well as infiltration when first seen.

The average duration of the nonulcerated cases from the date of their first symptoms up to the present time or death was 6 years, while of 17 of these cases who improved and are living the average duration is 13 years, and of the 8 who are worse or dead it was but 3 years 10 months. Total average duration of the 20 cases with ulceration was 3 years 2 months; of 5 cases that improved and are living it was 8 years 5 months; while of the fatal and deteriorated cases it was 2 years. Of the deteriorated cases, with and without ulceration combined, the average duration was 2 years and 7 months. This is somewhat longer than the 2-years' limit given by Bosworth for all laryngeal cases.

With regard to position of the ulcers, dividing them by the situation of the first or most marked ulcer, it was found upon the false cords in 20 per cent, on the commissure in 30 per cent, and upon the epiglottis in the same proportion; upon the arytenoids in 45 per cent and upon the true cords in 50 per cent.

Of the non-ulcerated cases 40 per cent were in the first stage, 32 per cent in the second, and 24 per cent in the third. Of those with ulceration 20 per cent were in the first stage, 30 per cent in the second, and 50 per cent in the third; thus showing a close relation between the condition of the lungs and throat.

The results are placed under the following heads: Cured, greatly improved, improved, and worse. These terms apply to the entire condition and not to the throat alone. The cured are those from whom all signs of ill health have disappeared and who have remained well not less than two years. The greatly improved are those who are practically well, but yet show some signs of trifling disability, or have not recovered long enough to be pronounced cured. The improved are those who, while they may have suffered and are still suffering from their battle with disease, yet show a tendency to recovery, but are still on uncertain ground. The worse include all the fatal cases and the few still living whose tendency is downward.

Seventy-eight non-laryngeal cases cured, 36 greatly improved, 30 improved, 57 worse.

*Laryngeal cases.*—Non-ulcerated: 9 cured, 7 greatly improved, 3 improved, 3 died, 2 worse. Ulcerated: 2 cured, 2 greatly improved, 1 improved, 10 died. Total laryngeal: Cured 11, greatly improved 9, improved 4, died 16, worse 2. Grouping together the cured, greatly improved, and improved, under the head of improved, we find of the whole 250 cases of phthisis 72 per cent improved. But of the 45 laryngeal cases only 49 per cent improved. The non-ulcerated cases, however, showed 68 per cent, and the ulcerated only 25 per cent improved. Taking the condition of the throat without regard to the ultimate fate of the patient, the results were much better, there being local permanent arrest of disease in 64 per cent, besides 5 cases which healed temporarily. Among the non-ulcerated cases, alone, 68 per cent showed a return to normal appearance in the larynx, while among the ulcerated cases, 50 per cent healed permanently and 3 cases, in addition, temporarily. With regard to the position of the ulceration the results were: Commissure, 33.3 per cent improved; true cords, 30 per cent; epiglottis, 17 per cent, while of the arytenoids and false cords none improved. To recapitulate, it may be said that of the whole number of cases, viz., 250, a little more than 2 out of 3 improved. Of the 45 who had laryngeal disease, 1 out of 2 improved. Of the 25 cases in whom there was laryngeal tubercular infiltration without ulceration, a little more than 2 out of 3 improved, while of the 20 in whom there was laryngeal tubercular ulceration only 1 in 4 improved, but of the 205 cases without laryngeal disease there was improvement in nearly 3 out of every 4 cases, the exact reverse of the laryngeal ulcerated cases. This shows, as was to be expected, that the laryngeal complication reduces the chance of improvement, and when it has proceeded to ulceration does so to the extent of 3 to 1. But even then, according to the opinions expressed by laryngologists practicing in low climates, these are far better results than have been obtained, and shows, I believe, that similar beneficial, retarding, and often curative effects which have been demonstrated in pulmonary tuberculosis treated in Colorado and other high climates are exhibited in laryngeal tuberculosis. That the results are not quite as good, though relatively so, is of course to be expected, as in all of these cases, and I have never seen a laryngeal tuberculosis without an accompanying pulmonary tuberculosis; there was the double disease and therefore the double burden to bear. Moreover, there is little doubt that the laryngeal complication in almost all, if not in all cases, indicates a tendency to a free dissemination of tubercle and generally an absence of any self-limiting tendency. There are undoubtedly some cases in which the laryngeal tuberculosis is derived from a local inoculation from the sputum from the tuberculous lung lodging on the abraded mucous membrane, but clinical observation leads me to believe that in the great majority of the cases the infection starts from within and not from without.

Taking the results upon the laryngeal disease alone, irrespective of the ultimate recovery or deterioration of the patient on account of the accompanying lung disease, we find that in 64.2 per cent there was arrest, and if we consider also the five in whom there was temporary healing, which broke down again under the strain of the last weeks of fatal pulmonary suppuration, we see that the percentage of improvement in the local laryngeal symptoms is not very far short of that of the simple pulmonary cases.

While I believe that, contrary to what was a common impression, viz., that high climates are injurious *per se* to tubercular laryngitis, they are positively beneficial, speaking as a generality; yet such results as I report could not be reached without in the majority, especially in the ulcerated cases, of careful local treatment. As Bosworth truly writes, after advocating topical measures, "in no ulcerative process, probably, are we able to detect in a less degree any reparatory

effort on the part of nature than in tubercular ulceration," and yet instances of spontaneous cicatrization have been reported by Bouveret, Virchow, Jarvis, and others. With regard to the nature of the treatment, it must vary according to the appearance of the parts from day to day, and all routine treatment is wrong. But in speaking of general principles, it may be said that the first essential is the toilet of the throat; that is, the removal of mucus, pus, etc., and the washing of the membrane, and this is in most cases best procured and with the pleasantest effects by a free spraying with Dobell's solution. The old injunctions were to use sedatives and avoid stimulants to a tubercular larynx. Now, in the majority of cases if the choice lay only between sedation and stimulation, I would say stimulate, while there is, often continuously and generally at the onset, hyperæmia and hyperæsthesia of some of the parts, yet the underlying condition is an anæmic one, the congestions are chronic, not acute, and the real good of treatment almost invariably comes from stimulation ranging from the mild stimulation of weak menthol and nitrate of silver solutions, etc., to the cauterization with lactic acid, and the scraping with the curette of ulcerated surfaces. Cocaine should of course be used to avoid pain of treatment, while for pain at other times a spray of anti-pyrine will generally give a more prolonged relief.

I should extend this paper beyond its proper limit were I to enter further into the details of treatment, but I may mention that astringents, iodoform, etc., are often of service. I believe in using the cotton applicator, the powder blower, and the spray, as the case demands; also, I must mention the valuable aid I derived from the Sass inhaler, particularly with the use of benzoin inhalations.

To conclude, it may be said that the foregoing facts would indicate that while tubercular laryngitis is always a grave complication at an altitude, as elsewhere, and when advanced is almost invariably fatal, yet in the earlier and medium cases high climates, with appropriate treatment, afford relatively, though not actually, as good a chance of arrest or delay in laryngeal as in pulmonary tuberculosis.

---

#### CLINICAL NOTES OF CASES OF TUBERCULAR ULCERATION OF THE LARYNX, TREATED BY THE KRAUSE METHOD AT THE THROAT AND CHEST CLINIC OF THE EMERGENCY HOSPITAL.

By T. MORRIS MURRAY, M. D., of Washington, D. C.

In 1886, Professor Krause read his now famous paper before the laryngological subsection at the fifty-ninth meeting of German naturalists and physicians at Berlin, in which he asserted that, when great debility was not present, under which circumstances he always advised against the treatment, no tubercular ulceration with which lactic acid comes in direct contact refuses to heal. He reported 14 cases successfully treated in this manner. To Heryng, of Warsaw, belongs the distinction of having first employed effective surgical procedure in the treatment of tubercular ulceration of the larynx. In his book upon the surgical treatment of tubercular ulcerations of the larynx he reports 13 cases successfully treated in this manner alone. Krause has an article in the May number, 1889, of the *Therapeutische Monatschrift*, in which he gives the history of 71 cases treated with lactic acid and the curette from 1885 to 1888, inclusive. Of these, up to the time of publication, 1889, 28 remained improved in condition, 7 dead, but not as a result of tubercular laryngitis, 8 the result unknown, 12 still under treatment, 8 sick when treatment was stopped, 8 died unhealed. At the Berlin congress in 1890 a day was given to the discussion of the treatment of laryngeal tuberculosis, and it was almost unanimously agreed that when properly treated with the curette and lactic-acid applications the disease was curable.

The literature upon this subject, particularly in the European journals, is voluminous. In America articles have been contributed by Delavan, Major, Weed, and others. One of the most recent publications is that of Dr. Hèlary, of Paris, in which he contrasts the medical with the surgical treatment of laryngeal tuberculosis. The conclusions at which he arrives are as follows: First. Laryngeal tuberculosis is not benefited by medical treatment. Second. Surgical treatment, on the other hand, ameliorates, in a certain way, dysphagia, dyspnœa, dysphonia. Third. Curetting the larynx causes the disappearance of the troubles of respiration and permits the avoidance of tracheotomy in certain forms of tuberculous laryngitis. Fourth. The extirpation of the infiltrated arytenoid masses has the most happy influence upon the dysphagia which it always calms. In permitting the patient to eat who is literally dying of hunger it prolongs his existence and contributes to the relief of the general condition. Fifth. Endolaryngeal operations are not followed, save in absolutely exceptional cases, by serious accident. Sixth. They have a happy action upon the ulterior evolution of the pulmonary tuberculosis, the progress of which seems to be retarded. Seventh. Surgical treatment does not act as a palliative merely; it can also, but in rare cases, cure laryngeal phthisis, as is proven by pathologic anatomy and in the clinic. Eighth. Curative treatment can be obtained in three ways: (1) By curetting the larynx, the more ordinary method; (2) by laryngo fissure, a procedure rarely employed; (3) extirpation of the larynx, an operation which has yielded one or two successes, but which must be rejected by reason of its too great gravity.

I have given these conclusions in full, because they embody so nearly the results of my own experience. I can not agree with him however if, as I understand him, he means to eliminate lactic acid in the treatment of tubercular ulcerations. I regard it as an indispensable aid in the treatment of many, if not most, of these lesions. Certainly this is true if the operations are done by any but the most skilled in such surgical procedure, and under such exceptional circumstances I think it has its value, producing coagulation upon the cut surfaces. It does away with reinfection from the pulmonary trouble, which nearly always exists in such cases.

In reporting the following cases treated under my direction at the Emergency Hospital of this city, I can claim nothing original in their management, scarcely anything of interest in their history. They are offered as a small contribution to the existing statistics.

*Case 1.*—A. S., white, female. Father healthy; mother died of throat trouble of four months' duration, and had cough before this developed; brother died at 16 of phthisis; sister living, asthmatic. Consulted me January 16, 1891. Had always been subject to colds, and in January, 1890, had grippe which lasted three weeks. A slight cough remained, from which she never entirely recovered. The following May the patient was treated by a laryngologist in this city for throat trouble and bronchitis. There was an ulcer which she could see upon left wall of pharynx; the epiglottis was said to be affected. In July she went to the country, and pharyngeal ulceration was healed in three weeks by application of sulphur. The summer was spent at Cape May. General health much improved; gained 7 or 8 pounds in weight. In September, had an attack of pleurisy which lasted for six weeks, and left her with a distressing cough. January 10, 1891, had pain for first time and difficulty in swallowing; no night sweats or hæmoptysis; no evening elevation of temperature. Appetite and digestion good; sleep disturbed by cough; menstruation normal; voice impaired. Examination of pharynx discovered an oval ulceration upon upper portion of the back wall, on the right; no indication of previous ulceration upon the left side; epiglottis immovable, indurated and much thickened; ulcerated nodules over whole of laryngeal surface; large ulceration on right ventricular band. Ary-epiglottic folds infiltrated; tubercle bacilli found in the pus from the pharynx and in the sputum; the apices of both lungs are consolidated and beginning to soften. Fifty per cent solution of lactic acid was applied to the pharyngeal and laryngeal ulcerations, which relieved the pain. February 22, the pharyngeal ulceration was curetted; application of lactic acid continued; the pharyngeal ulceration entirely healed in two weeks. The epiglottis and right ven-

tricular band were curetted March 22, and acid applied; the ventricular band cicatrized, but not the epiglottis; there was no pain on swallowing. In May she was very much exhausted by a profuse and painful menstruation, and was sent to the seashore for a week. Upon her return an ulceration was seen in the interarytenoid space. This was curetted, and the epiglottis the week following; the latter was permanently benefited, the former only temporarily so, and it was necessary to operate again June 17. Another confinement to the house greatly weakened the patient and the ulceration increased in extent and activity. Subsequent applications again held ulceration in check and relieved pain. The general exhaustion was increased by rapid softening of pulmonary deposits, and death ensued September 3, 1891.

*Case 2.*—James J. White, age 24. Family history good; has had a bad cough for two years; aphonia for six months; for two months has been spitting blood; is very much emaciated, hectic; painful deglutition; all of both lungs involved; cavity in the left lung; ary-aepiglottic folds and epiglottis infiltrated; ulceration of vocal cords and ventricular bands; large granulations in interarytenoid space. General treatment: Lactic acid applied to larynx, which relieved pain and lessened difficulty in swallowing; owing to extreme debility the patient was unable to come to hospital regularly. He was seen April 7; the uvula was then enlarged, of a firm and nodular appearance; this was amputated with snare and the base healed rapidly. May 7, superficial indolent ulceration on the left side of the soft palate; lactic acid applied. May 20, ulceration has spread; soft palate, dotted with small spots; whole palate edematous and infiltrated. June 12, soft palate a mass of broken-down nodular granulations, with tubercle bacilli in the pus; excruciating pain in swallowing; left side of palate curetted, followed by application of pure acid; relief so marked that the right side was treated in a similar manner and lactic acid applied every other day, until the ulcerations were entirely healed. Patient died July 10, 1891.

*Case 3.*—A. S., colored, widow, age 41. Family history good; had grippe in the winter of 1890; cough began to be troublesome in January, 1891; hoarseness supervened in March; no appreciable loss of flesh during the year and strength well preserved; the patient has an annoying cough at night; occasional night sweats; no hæmoptysis; painful and difficult deglutition; retraction of inferior claviclar region on left side, dullness of both sides; also broncho-vesicular respiration; occasional râles in both inferior claviclar regions, prolonged expiration in left; voice reduced to a whisper. Examination of the pharynx and larynx showed a large ulceration upon left side of posterior wall of the pharynx extending one-fourth inch above the level of the soft palate, palatine fold very much swollen and inflamed; ulceration in interarytenoid space and upon the right cord; ventricular bands thickened and very much inflamed; tubercle bacilli found in the pus from the pharyngeal ulceration and in the sputum. The patient was put upon general treatment and fuchsin applied to the larynx for two weeks. At the end of this time, the granulations having increased in size, it was replaced by a 50 per cent solution of lactic acid, applied twice a week. October 22 the pharyngeal ulceration was curetted and the acid applied. At the end of the week the tissue had again broken down. October 27 the whole of the pharyngeal involvement was again curetted and entirely healed in seven days and has given no trouble since. December 15, superficial ulceration appeared upon the superior surface of left arytenoid, and sudden increase in edema of the ventricular bands; treatment continued. January 5, ulceration upon the right cord healed; the ulceration in the interarytenoid space is the only active process remaining. January 13, application of acid continued. January 21, sudden edema and involvement of left ventricular band, margin of cord, and left arytenoid. February 25, ulceration of ventricular band and arytenoid cicatrized; left cord presents raw, lumpy granulations; treatment continued. March 31, no ulcerations visible in larynx; voice much improved; lungs in about the same condition as when first examined; general health improved and gain in weight; no evening fever. It is now eighteen months since the last operation. There has been no return of ulceration in the larynx. The normal weight has been regained and the patient is apparently in perfect health. The voice, however, is still impaired owing to what I think is an unusual accident in such cases. The vocal cords are united by a thick band of cicatricial tissue for nearly two-thirds of their entire length. This remains owing to a disinclination on the part of the patient to submit to the operation necessary for its relief.

*Case 4.*—S. C., female, colored, age 29. Examined April 25, 1891; pulmonary tuberculosis; deposits in the apices of both lungs; irregular granulations in the interarytenoid space; lactic acid, 50 per cent, was applied twice a week. There was a gradual disappearance of the granulations and cicatrization of the ulcer.

During the next month the patient failed rapidly. An ulceration was seen extending down the posterior wall below the cords. No return of the ulceration in the interarytenoid space. The patient discontinued her visits to the hospital, and, as I learned subsequently, died. In this case a severe edema, the only instance in my experience, followed one of the applications of lactic acid. It yielded, however, promptly to scarification.

*Case 5.*—White, male, age 56. First visit, May 6, 1893. Pulmonary and laryngeal tuberculosis with emaciation, anorexia, night sweats, etc.; both lungs were involved. There was a decided thickening and infiltration of the arytenoids and ulceration of the interarytenoid space. A superficial ulceration was also found on the upper edge of the left ventricular band. Lactic acid was applied twice a week from May 6 until June 3. Both ulcers were healed and there was a marked relief of the subjective symptoms. The patient's voice was strong and clear; general health improved. Last visit June 10.

*Case 6.*—White, female, age 29. First visit, June 26. Pulmonary phthisis; areas of softening in both lungs, with small cavities in right apex. There was an ulceration a quarter of an inch in diameter, with small granulations springing from its base, in the interarytenoid space. The voice weak and husky; deglutition painful. Patient was treated with lactic acid twice a week from June 26 to August 7. On the latter date the ulcer had cicatrized, the voice was clear, and the patient had no pain in the larynx. Last visit, August 7.

In three of these cases it can scarcely be claimed that life was much prolonged, but they were spared the terrible suffering always attendant upon this disease under former methods of treatment. In the third case I think it can fairly be claimed that the patient is cured. It will be observed that in cases 1 and 3 the laryngeal and pharyngeal ulcerations appeared practically at the same stage of the disease. In case 2 the involvement of the uvula and soft palate occurred when the patient was in the last stage of decline; yet in all the ulcerations which could be easily reached and thoroughly treated healed readily, while those in the larynx resisted treatment to a greater or less degree. These observations would seem to indicate that the limitations placed by Krause upon his treatment are unnecessary, and that desirable results in some cases can be obtained even though great debility should exist, whenever lactic acid can be brought in direct contact with the granulations. The management of laryngeal phthisis must always be attended with embarrassment to the laryngologist, owing to the extreme difficulty, if not impossibility, often, of reaching the whole of the diseased surface. With pharyngeal and buccal phthisis the case is different. There is now, I think, no reason why these most painful complications of tuberculosis, conducing, as they always do, to the speedy and fatal termination of the disease, should not be completely under the control of the physician.

---

#### PRELIMINARY NOTE ON THE USE OF THE FORMATES IN ULCERATION OF THE PHARYNGEAL AND LARYNGEAL MUCOUS MEMBRANE.

By E. L. SHURLY, of Detroit, Mich.

The caustic property of formic acid, whether derived from insects or plants or manufactured synthetically in the chemical laboratory, has for a long time been observed, and also antiseptic properties belonging to it have been noted from time to time, although the literature of the subject is very meager. Theorizing that this agent or its combinations as existing in animals and plants might be a natural chemical agent, in some way designed to protect their bodies from extraneous deleterious influences, it occurred to me to test the action of the various salts of formic acid upon some of the lower animals for the purpose of ascertaining their degree of usefulness in the treatment of general septic diseases, especially the so-called "tubercular diseases." Accordingly in 1891, in the laboratory of Harper Hospital, Dr. P. M. Hickey made formic acid from oxalic acid and glyc-

erin, according to the ordinary process; and directly from this made formate of sodium, formate of calcium, formate of ammonium, formate of barium, formate of copper, formate of iron, and the iodoformates of iron, sodium, calcium, and ammonium. We next tested the effects of these various salts upon such of the lower animals as mice, rats, guinea pigs, and monkeys. The formate and iodoformate of copper, sodium, calcium, barium, and iron were all found to be poisonous to mice and rats in the proportion of from one-half to 2 grains when introduced by hypodermic injections. They were also fatal, but after a longer lapse of time, when introduced into the stomach of these animals in somewhat larger doses. Rabbits and guinea pigs bore from 5 to 10 grains of formate of sodium, ammonium, and iron, but rapidly succumbed to the same dosage of the copper, calcium, and barium salts. The iodoformate of sodium was also borne in 5 to 10 grain doses by the larger animals. The iodoformate of sodium and ammonium proved to be antitoxic to pus and tubercular sputum in rabbits, as shown by the experiments of injecting these animals with each of these toxic materials, respectively, and then a short time afterwards injecting them with the above-named chemicals. One animal only, out of several, died from ordinary septicæmia. An extract of sputum, obtained by treatment with alcohol and phospho-molybdic acid, when injected into a mouse produced a convulsive chill, lasting until death, which occurred after eight hours. The same extract when mixed with an equal quantity of a 10 per cent solution of iodoformate of soda had no toxic effect. Pure cultures of the *staphylococcus pyogenes aureus*, when mixed with formate of soda and injected into the peritoneal cavity of a rabbit, did not produce any toxic effect. Formate of sodium and ammonium only was given to monkeys by the mouth and by hypodermic injection. It was found that of all these salts formate of sodium and formate of ammonium especially were non-poisonous. A large-sized Rhesus monkey was given 60 grains, by the mouth, of formate of sodium in four doses, during a period of twelve hours, with the effect of reddening the tongue only, causing salivation and an inordinate appetite. From these preliminary investigations it was decided to turn our attention to the human subject, confining ourselves to the use of the salts of sodium, ammonium, and iron. Accordingly these were employed in hospital practice upon various patients, who were suffering from different forms of phthisis, especially laryngeal phthisis. These agents were also used upon a few patients who were suffering from epithelioma, lupus, and sarcoma of the throat.

One patient (Mrs. C.), who was suffering from general tuberculosis, was given ammonium formate in from 1 to 10 grain doses for over a period of two months, beginning October 28, 1891. It was administered to this woman, both hypodermically and by the mouth, from three to six times daily. Its effects were quite marked, being manifest occasionally by increase of appetite and extra salivation. After awhile its use would have to be discontinued on account of the supervention of stomatitis, but no sensible effect was observed on the general course of the disease. The hyperæmia of the buccal mucous membrane would soon subside upon the discontinuance of the drug. We also administered to this same patient the formate of iron with decided tonic effects, but its long continuance seemed to produce irritation of the intestinal tract. The same effect was observed from the use of the sodium formate.

Another patient (J. N.), suffering from severe tubercular ulceration of the larynx, was treated internally by the administration (as in the former case) of formate of sodium or ammonium, without very much effect upon the local lesion. Internal administration was stopped and the drug was used locally by means of spray and afterwards by insufflation, the insufflating powder consisting of sodium formate and starch, of each equal parts. Under the local treatment there was a marked cicatrization of the more recent ulceration, but among the deep ulcerations which

reached the cartilages of the larynx complete granulation and cicatrization could not be brought about. Notwithstanding this was a hopeless case, we observed that at the time of death the laryngeal ulceration was certainly one-half less than when he was "put upon" this local treatment. In a hopeless case of sarcoma (N. G.), where the ulceration of the pharynx was very extensive, formate of sodium was used by insufflation, and spraying three or four times daily for the purpose especially of testing its local action on such extensive ulcerated surfaces. To our surprise, even in this case we found that cicatrization of the superficial ulcerations here and there would take place in spite of the rapid breaking down of the tissues all about this region. Besides this, its effects were so marked in giving ease to the patient that he was constantly besieging the nurses to use it. These three cases cited were treated simply to test, under the most disadvantageous circumstances, the effects, if any, which these salts might have locally and not with any hope of producing permanent benefit. Deriving some encouragement from these observations, we have since used from 5 to 10 per cent solutions of the ammonium and sodium formates in a number of cases of laryngeal and pharyngeal ulceration of a specific, a tuberculous, and epitheliomatous nature. In the more benign cases cicatrization has promptly occurred from the use of these salts, although with many of them, through the unfavorable general progress of the disease, the effect has not been permanent. However, in purely benign ulcerations of mucous membrane these salts have been found very efficacious in producing healthy granulations and prompt cicatrization. It therefore seems to me that these agents are worthy of more extended trial in the treatment of pharyngeal and laryngeal ulcerations. The insufflation of equal parts of formate of sodium and starch seems to produce no direct irritation, unless used more frequently than about four times daily. In ulceration of the throat accompanying scarlet fever, and in diphtheria, formate of sodium or ammonium may be used by spraying or insufflation as often as once in two hours, without producing much if any irritation of the surrounding membrane.

I think formate of iron deserves a more extensive trial than it has had, for its good effects are certainly equal to some of the other salts of iron, especially in the septic diseases. The application of these salts undiluted to the mucous membrane (with the exception of copper) causes little or no pain. But a 10 per cent solution applied to the larynx, where the membrane is hyperæmic from recent disease, causes a stinging pain for a few minutes. But generally speaking, there is no smarting as a result of its application in the strength above indicated. However, in some instances where sodium or ammonium formate is applied directly to the mucous membrane it causes considerable sharp pain for a period of from five to ten minutes, but this is not the rule.

I do not consider it necessary to weary my hearers by lengthy details of all the cases in which these several salts have been used, because I think that further observation is requisite in order to place a proper value upon them as remedial agents.

---

#### DISCUSSION.

Dr. JOHN N. MACKENZIE, Baltimore. I have been very much pleased to hear these three papers. We now no longer regard laryngeal tuberculosis as a necessarily fatal disease; we are gradually getting to that position where we can tell a patient that in a case of moderate ulceration of the larynx, and especially of the pharynx, we can cure. I was very much interested to hear from Dr. Solly that these cases do so well in Colorado, and I am exceedingly glad to learn of his good results.

Dr. PRICE-BROWN, Toronto. I would like to say a word as to laryngeal operations in tuberculosis of the larynx, from my own limited experience. I have in one case, I think, seen a complete cure of infiltration with ulceration of the larynx by operative measures. Briefly, this case was that of a lady who came to me first in June, 1891. She was 27 years of age and unmarried. Her mother died of tuberculosis. She had been suffering from hoarseness for a year and a half and during the latter months of this time was almost completely aphonic; her temperature was  $100^{\circ}$ ; she complained of soreness over the apex of the left lung. On examination I found solidification, bronchial breathing, and all the evidence of tuberculosis. Examination of the larynx revealed a large infiltration between the arytenoids with the ulcer projecting toward the epiglottis and extending to the level of the vocal cords. The cords were congested and she could not vocalize because it was impossible to bring them into juxtaposition. I applied a pretty strong solution of cocaine and made two operations with the galvano-cautery upon this growth, at an interval of a week. This did not have as much effect as I desired; there was some sloughing. During the summer of 1891 I curetted the growth a number of times. I did not use lactic acid, but what was much preferable to the patient, a solution of menthol in a strength of 5 to 10 per cent in albolene. This was used daily, and about the end of the year her voice had almost returned, the ulceration had ceased and showed cicatrization. I have seen her often since, and her voice is now entirely restored; there is complete healing of the ulceration; the lung is what I call fibrous, there is a creaking sound over it; there is no fever, but some cough. I saw her three weeks ago and her voice was clear. I think in this case there was complete cure by operation, but I suppose eventually she will die of tuberculosis of the lungs.

Dr. S. K. MERRICK, Baltimore. I am very glad indeed to hear of cases so near home as Washington being cured of tubercular laryngitis. One case in particular related by Dr. Murray, where he is sure the patient is well, I am particularly interested in; also the one to which Dr. Brown has referred. Personally I have never seen a case of laryngeal ulceration of tubercular origin that was cured. For some years there was a great deal of skepticism as to the possibility of such a result, but the cases have so multiplied and cases are so numerous it is now a notable fact that cases of tubercular laryngitis get well, temporarily, at least. It seems to me it is a distinct gain to know that we can do anything in these cases. I have a case of laryngeal ulceration that I saw this morning. When the case presented himself about six months ago there was simply slight swelling of the arytenoids, and there was a cavity in the right lung. The patient was sent to Atlantic City and he took on 12 pounds of flesh there in three weeks; still the throat trouble did not improve. He has been under treatment from time to time, and I have been sending him to the country a good deal. I believe to a certain extent, as Osler once said to me he believed, that "the country will do more for phthisis than any doctor can do." I believe that is certainly the case unless there are laryngeal complications. This patient spends most of the time in the country. All my cases of tubercular laryngitis go on and die. I have tried lactic acid and nearly every drug that has had a reputation for curing these cases. I may say that in the last twelve years I have had about 2,000 cases of pulmonary tuberculosis from outdoor clinics and I have never seen a case with tubercular laryngitis that has healed where there was the bacillus tuberculosis in the sputum, and I am very glad to find, so near home, gentlemen testifying to facts so favorable that are undoubtedly true. I feel utterly without hope in these cases when I take them. Any advance along the line of even temporary improvement is to be accepted with thanks, and it is to be hoped that reports will be even more favorable in the future as our knowledge increases.

Dr. H. HOLBROOK CURTIS, New York City. I have been extremely interested in this discussion, especially in the remarks of Dr. Solly. I wonder if he realizes the weight of responsibility resting upon him in his peculiar position in the West and his great opportunity for observation in these cases. How excellent are the conditions when the patient goes to a mountain resort free from the cares of his business, where he is buoyed up by the enthusiasm and hope which must be more or less inculcated by association with the large number of patients who are improving. The statistics of his paper are very flattering and must of necessity be a little more favorable than the statistics we can show. It is very satisfactory to hear of any hope that can be given in cases of laryngeal tuberculosis. I reported four cases a year ago at the Academy of Medicine in which I thought three had made absolute recovery, but another year has passed and two of these cases have gone back; their throats have become reinfected, although they have been very careful in the use of peroxide of hydrogen and kept their throats very well cleansed. The one case I may still claim as a cure was a most peculiar one. This young man was 19 years of age. When he came to me his left lung was consolidated at the apex and his throat had the appearance of three Malaga grapes. The epiglottis was infiltrated and edematous, and both of arytenoids filled up the entire larynx so that I could only get an obscure view of one cord. I gave no hope whatever in this case; nevertheless, I scarified and curetted according to the method of Krause, applying lactic acid thoroughly, and to my surprise there seemed to be an improvement. As soon as the edema was reduced I saw that there was entire absence of the left vocal cord. When the throat got a little better he developed a perichondrial abscess, which I opened externally, and nearly one-half of the thyroid cartilage came through as a sequestrum and was removed. I kept a drainage tube there for nearly three months, when the ulceration of the throat entirely disappeared; afterwards the thyro-arytenoid muscle repaired itself and the vocal cord was reproduced as a flabby band on that side. That was eighteen months ago, and he has had no return of the throat trouble; but I am told that his other lung is affected and that he is running down and losing flesh from pulmonary tuberculosis. I do not think we ought to feel too much encouraged by the reports we have heard read, but we may hope to give patients suffering from this disease some relief. Two years is scarcely enough time in which to decide that these cases are cured. If we took five years our statistics of cure would be very much less. I think the return of the disease is almost inevitable. One per cent would seem to me a very flattering figure to place as the probability of cure in tubercular ulceration of the larynx.

Dr. D. BRYSON DELAVAN, New York City. It is not often that three such papers are brought together at one time. Each is in itself extremely interesting, instructive, and valuable, the one to a remarkable degree offsetting the others, and each representing, as it does, a distinct basis of treatment. With regard to tubercular laryngitis there was formally no hopeful condition. Comparing the prognosis possible in many cases now, and I am not inclined to take a more sanguine view of recent advances than are others, in the last five years progress has certainly been made, although the fact remains that even before these new methods of treatment were proposed cases of tubercular laryngitis were known to recover. I have had several such, in which recovery was due to climatic influences of a favorable nature. Cases have also been seen, although very rarely, where tubercular ulceration has been arrested by persistent local treatment; I mean strictly therapeutic treatment. So there were two resources by which it was possible in rare instances to arrest tubercular laryngitis. When Prof. Krause and Theodore Heryng offered their suggestions a new field for research and experimentation was opened. Unexpected success attended their methods in that these patients did get well of tubercular laryngitis. That this is a fact I know, for I have seen

Dr. Krause take a case of advanced tubercular laryngitis in which it seemed that no help could be given the patient, and after performing what seemed to be a most severe operation have found that in forty-eight hours the patient was greatly relieved. I have operated upon cases myself where cicatrization has followed the removal of diseased tissue from the larynx and the standard treatment with lactic acid employed. Lactic acid is a good method of treatment, combined with curettement, or the extirpation of the diseased tissues. It is efficient in some cases where simple topical treatment would be unavailing. I had the privilege this winter of studying some cases under the care of my friend, Dr. Trudeau, in the Adirondacks, which showed very remarkable results in the healing of advanced laryngeal disease. I saw in the sanitarium at Saranac five cases in which advanced ulceration had been arrested. The treatment consisted of the injection of a modified tubercular lymph, prepared on a totally different principle from the lymph of Prof. Koch, and practically deprived of the irritating and dangerous qualities of the original tuberculin. Not only did these laryngeal cases do well under the injection of tuberculin, but cases of pulmonary tuberculosis have done well also. Since the date of the above observation, a period of ten months, all of the above cases have done well, and a number of new and successful ones have been added to the list. Each of these things marks an advance in the treatment of this disease, cases of which are so often set aside as incurable. It is immaterial whether the patient lives indefinitely or not; it is an immense advantage that he should be left to live out the time allowed him by his tubercular disease without tubercular laryngitis. If we can relieve the patient for a year, a month, or even a week, we are fully justified in bestowing all possible pains and labor in our power to help him. It is not necessary for patients who die ultimately from tubercular disease to have a recurrence of laryngeal symptoms. The reports of Prof. Krause show that a considerable number of his cases have been cured; that is, permanently relieved of laryngeal ulceration and all the attendant symptoms that go with it, although they have finally died of the pulmonary trouble. That is certainly a vastly better outlook than we had ten years ago, and it is certainly a subject of great rejoicing that we can relieve these patients, if only to a limited and very moderate degree. When it comes to the treatment of special cases, Dr. Murray has dealt with such as most of us will have to meet with, namely, those who must remain at home. Unfortunately tuberculosis is a disease which should be confined to the wealthy. The poor man ought not to have it. Unfortunately, he will have it, and we shall have to help him; and anything that will help him is greatly to be desired. We have the above resources, which can be carried out at home, to the great relief of the patient. The conditions described by Dr. Solly are truly, on the other hand, Utopian. They are the happiest, best, and most favorable conditions the tubercular patient can be placed in, namely, first, to be able to live in the most beneficial climate possible; and, second, in that climate to receive the most skillful and admirable treatment that can be given him. Under this second condition many of our health resorts are unavailable. We dare not send our patients to them, because there is no one there to look after them, and, if for no other reason, I think the writer of the paper deserves gratitude for the fact that he has been one of the pioneers in establishing the idea that a patient can be sent to a first-class climate and there receive first-class treatment. It is only a question of time when such sanitarium will become more widely distributed, and we can then select the climate most beneficial for a given subject. This experiment, carried out in Colorado Springs, is certainly one of the most interesting and valuable ever attempted in this or any other country. One word about the Krause treatment: While it may not be applicable in every instance, it certainly has a place in our armamentarium, and the successful work of every man in this direction is a benefit to us all. It would be very valuable if in discussing the matter with our patients we could

refer to such excellent work as we have just heard of, not only from one but from a large number of good operators and careful observers in this country.

Dr. E. FLETCHER INGALS, Chicago. Years ago I stated at the American Laryngological Association that as a rule laryngeal tuberculosis would get better if the patient's general condition improved, but the reverse was also true. I think the rule is correct, but we have been shown to-day that there are a considerable number of exceptions, more than I had supposed possible. I was particularly struck with the remark that there seems to be something peculiar to the German people that enables them to bear severe treatment better than others, and perhaps the same may be true of negroes. My patients will not usually tolerate such rough handling, but certainly Dr. Murray's results were most excellent. I confess that after Dr. Delavan's report I had so little confidence in Krause's method that I did not try it, though I used the lactic acid without the curette. I did not fully understand whether Dr. Murray meant to fully coincide with the statements he quoted from Henry or not, but for fear he did not I want to say that I think they are not correct. For example, I understood him to say that laryngeal tuberculosis is not benefited by medical treatment. I am quite satisfied from a very considerable number of cases that medical treatment, even internal treatment, but particularly topical medical treatment is of very great advantage, and that many cases recover under this course; indeed, I believe many more than would be benefited by any surgical procedure. General treatment I consider of prime importance. Topical treatments have seemed to me of special value in relieving the sufferings of the patient and thus permitting better nutrition. Dr. Shurley, whose paper we have heard, sent me some of the formate of soda to try in laryngeal tuberculosis. I tried it in two or three cases, but not sufficiently to speak of its efficacy. I have used various other local remedies and have tried lactic acid, but have not used the latter thoroughly. Lately I have been using a remedy which at least in two cases seems to have been of very great value. In one of these cases the patient suffered from extensive tuberculosis of one lung. There were many tubercle bacilli in the sputum, but the larynx was not ulcerated, though both larynx and trachea were congested and there was some infiltration of the larynx. Under the influence of this remedy, the terchloride of iodine, he improved immediately, and his improvement was so great that the patient, who is a physician, calls himself well, though he occasionally catches cold and then comes in for treatment, one or two applications as a rule being sufficient to make him feel all right for a couple of months. I am satisfied that the terchloride should have the credit, for he says this is the only remedy that ever did him any good. The other case referred to was one in which there was extensive infiltration, and ulceration of the left ventricular band extending down to the cord. Under the use of the terchloride of iodine the infiltration has largely subsided, at least 50 per cent having disappeared, and the ulcer appears to be healed. There is a small excavation still, but it does not seem to be an open ulcer. The terchloride of iodine is specially valuable for the reason that when applied to a surface on which there is purulent secretion it becomes decomposed at once, the iodine being set free in a nascent state which is thought to be more than under other conditions. I use it in the strength of from 1 to  $2\frac{1}{2}$  grains to the ounce of distilled water as a spray. Dr. Curtis's remark that a patient must remain well from two to five years before he can say he is cured is very true, but if we can cause the ulcer to heal we do the patient a great good, even though a cure may not be effected.

Dr. SOLLY. I thank the section for the consideration they have given to my paper. What Dr. Curtis said about responsibility I think I feel very fully. One thing that particularly strikes me in regard to this disease and tuberculosis generally is that we have in Colorado Springs the opportunity of observing what may be termed its natural history. So many cases of tuberculosis die in low climates so

much earlier than in high, even the fatal cases are usually more prolonged in Colorado, and we have the opportunity of seeing the disease in its various phases, better perhaps than you do at sea level. Also, we are intimate with our patients, we observe them on the street, we know how they are living, what they are doing, and therefore there are many aspects of tuberculosis we see that do not show themselves to you. As regards the point of patients being buoyed up by the climate, that is true. Some are extremely hopeful when they come on the high ground. It has a marked effect upon perhaps 50 per cent, but on the other hand an equal number are homesick, suffering from the absence of friends and business; they are worried and fret and often die. Unquestionably two years is too short a time to pronounce any case cured, and in my reports no cases are given as cured in two years although some are reported as greatly improved. I have avoided using the term cured unless at least five years have passed, and in many cases longer than that; some observations go back seventeen or eighteen years. I could not burden the paper with fuller details of these cases, but I hope to publish them some time *in extenso*.

Dr. Curtis spoke about the return of the ulceration in the larynx. My statistics cover this point, but what astonished me very much, and Dr. Ingals also referred to it, is the fact that quite frequently when the patient was running down and dying of general tuberculosis the larynx remained healed. My observation has been when the ulceration is treated, getting down to what is called in the West "bed-rock," there is seldom a return of ulceration in the same spots, though it may occur elsewhere if the patient's general condition deteriorates. Of course healing the throat is not necessarily curing the patient, but he is relieved from one of the most painful deaths, viz., that from tubercular laryngitis. A very interesting case illustrating the difference between healing and cure of the tuberculosis was that of a gentleman whose larynx is now in the Army Medical Museum. He was in the Navy and in good health until he was attacked with an acute laryngitis and bronchitis, which became tuberculous. Aphonia continued and a chronic laryngitis, but the bronchitis disappeared. He went on the Greely expedition and improved very much in the dry cold, got strong and vigorous, but his voice did not come back. On his return, finding himself running down, he went again on an Arctic expedition, with the same results, and so came to Colorado. He was brought to me for examination by another physician. His larynx was unquestionably tuberculous, but no ulceration was then visible, although there were some few papillomata on the commissure, looking as if an ulcer had healed. There was consolidation at the apex of one lung; he was somewhat affected constitutionally. I did not see him again for about six months. In the meantime he was running about the country and overtaxing himself, and was brought again to me complaining of soreness of the throat and continued aphonia. His physician then placed him in my hands for treatment. There were several ulcers, and one at the base of the epiglottis had perforated. Under radical treatment the ulcers healed, though signs of infiltration remained and the voice was but little improved, the dullness at the apex of the lung cleared up, and his general health became excellent. He started to drive from Colorado Springs to Kansas City in an open gig, and arrived East in fine condition. Dr. Solis-Cohen then examined his larynx and reported it healed. After six months' residence in Washington general tuberculosis of the peritoneum and meninges came on and fresh ulcers appeared in the larynx, though not in the old spots. This case shows that there may be very marked local results from treatment even when the general tuberculosis is not cured. It is possible had this patient remained in Colorado, as advised, that he might yet be living. However this may be, all my clinical experience warrants the belief that laryngeal is as well suited as pulmonary tuberculosis for treatment in high climates.

Dr. T. MORRIS MURRAY, Washington, D. C. It has been a great pleasure to me to listen to Dr. Solly's paper. The results of the treatment he gives there are by far the best published in this country, and suggest to me what I have thought was perhaps one of the reasons why we get such different opinions as to the value of these methods of treatment in tuberculosis; that is, that the climatic conditions under which the treatment is instituted influence very materially the result. As to the medical treatment of which Dr. Ingals speaks, I must confess that having carefully followed the history of the medical treatment of laryngeal tuberculosis it seems to me to be simply a record of disappointment and failure. I may possibly undervalue medical treatment in such cases; I refer to local treatment. While undoubtedly it has its advantages when combined with the removal of the cause of the disease, I think that time is wasted in their employment when it is possible with the curette and lactic acid to destroy the cause of the trouble. It is particularly gratifying to me to hear Dr. Delavan speak with enthusiasm upon the surgical treatment of laryngeal tuberculosis. This is so because he was the first in this country to call attention to the subject. His continued enthusiasm is a high tribute to the excellency of this method of treatment, which to me certainly appears far superior to any other heretofore suggested.

---

#### THE UTILITY OF THE ELECTRO-CAUTERY SNARE.

By HANAU W. LOEB, M. D., of St. Louis, Mo.

Since the introduction of the electro-cautery snare as an agent for removing neoplasms and hypertrophied tissues in the nose and throat three facts have been well established: (1) One may operate without the occurrence of hæmorrhage; (2) one may operate with greater celerity; (3) one may operate with more precision. The first of these stands without an argument; all must recognize the influence of the red-hot wire in staying the flow of blood. The second, while no less a fact, still admits of some discussion. For while there is no necessity for wasting time in removing an enlarged tonsil by a knife or a tonsillotome, if it is desired to be accurate in removal, in other words, if a certain portion is to be removed, the operation with a snare requires far less time. In removing polypi the most partisan advocate of the cold snare will admit that it consumes far more time than the electro-cautery snare. But it is in reference to the last of this trinity of utilities that special stress should be laid, viz., the accuracy of removal. No one can hope, in face of the circumstances attendant upon pharyngeal operations, to be as accurate with the knife, scissors, or similar instruments as he can with the snare, which limits so exactly the line of removal. A patient may twist and turn as much as he pleases, and may indulge in gagging and the like, but when the snare has once been placed in proper position the operator may feel secure as to the amount of tissue he is going to remove. The cold snare is as accurate an instrument as the electro-cautery, but it does not rise to its plane of equality in so far as prevention of hæmorrhage and celerity are concerned. To consume half an hour in biting off a growth is by no means pleasant to the patient and is almost as annoying to the physician. There are other advantages of somewhat minor importance, such as greater ease of obtaining patient's consent to a simple operation, less pain, the decreased danger of injuring other organs and tissues, and the ability to perform two operations at the same time, where, under a form of operating without an absolute control of hæmorrhage, a second operation, on account of the flow of blood, would be precluded. The electro-cautery snare is therefore of utility in the following operations: (1) Removal of nasal polypi and tumors; (2) removal of redundant mucous membrane; (3) removal of tonsils; (4) removal of the uvula.

*Removal of nasal polypi and tumors.*—Among specialists the removal of polypi by the forceps has long since been tabooed and to the cold snare has been assigned the burden of popularity. As between the cold and the electro-cautery snare, there is to my mind no reason for hesitation in making a choice. The snare principle is the same in both, the manner of effecting the removal different. Tedious and failing to arrest hæmorrhage unless the wire be tightened very gradually, the cold snare is compelled to give way to the electro-cautery, which accomplishes the operation in an instant, occasions absolutely no hæmorrhage, and cauterizes the base of the tumor, thereby exercising an influence which in many cases at least prevents the return of the neoplasm. The application is as easy in one case as in the other, though until one is familiar with the electro-cautery instrument the wires attached to the handle may sometimes interfere. This objection, too, will be dismissed by a new handle which will not require the wires to be attached when applying the snare, a handle which I hope soon to have the pleasure of perfecting and of presenting to the profession. Far more polypi may be removed at one sitting. The act of removal in the one case requires but an instant, and in the other case from ten minutes to half an hour, depending upon the operator's other engagements. Less pain is occasioned by the electro-cautery snare, for the cocaine effect will not have worn away before the operation is completed. Farther application is accordingly obviated. After effects are no more common or severe than those following other methods of operating. This decision is the outcome of observation of a large number of cases during the past three years. During that time in over a hundred operations for nasal polypi no complication beyond the natural consequence of any surgical treatment has resulted, save in one case which was followed by otitis media, with which, however, I can not charge the electro-cautery. The operation was performed early in the morning of the 4th of July, 1893, and the patient carelessly stirred around all day, notwithstanding the inclement, damp weather. From this attack he very readily recovered. I do not wish to be understood as advocating the electro-cautery snare operation as a radical cure for polypi in opposition to the method of removing the diseased turbinate which primarily occasions the disease. I have too often seen the good effect of the latter operation. The fact still remains that the polypi are better removed by the electro-cautery snare; the other operation may, if indicated, be performed later. In all pendant nasal tumors, and in all those where it is possible to engage a wire around them, the electro-cautery is to be preferred to the cold snare, the reasons being the same as in the case of polypi, with a stronger argument in regard to its hemostatic power. Such tumors are often very vascular.

2. *Removal of redundant mucous membrane.*—In regard to the removal of redundant mucous membrane a similar condition of things prevails. As there is greater liability to hæmorrhage than in the case of polypi, the arguments urged before are multiplied. So kindly does the mucous membrane respond to this method of removal where it is indicated that I am safe in the conclusion that once tried it is sure to be adopted.

3. *Removal of tonsils.*—Tonsillar hæmorrhages are rare, but they are not so uncommon as to cause those who operate frequently to lose sight of their possibility. As the tonsillotome and the knife permit bleeding without restraint, it behooves the operator to lessen the chances if possible. The operation with a tonsillotome is too thoroughly ingrafted in the practice of the profession to expect a sudden change in the use of the instrument; it is too easy of performance to be cast to the wayside for what to many is an unknown quantity, and yet, after an experience not inconsiderable, I feel that my earliest expectations have been more than confirmed; truly no more thorough a realization could be desired. With the tonsillotome, in addition to the probability of hæmorrhage, no one can be very accurate; that is to say, the portion of tissue removed is apt to be greater or less

than was intended. When the electro-cautery snare, on the other hand, is used, precision is the rule, for the wire marks effectually the tissue desired to be removed. There is no danger of wounding the palate; no necessity of making a hit-or-miss thrust; no sudden action necessary on account of the restlessness of the patient; you may remove as much or as little as you wish. The method of operation is easy; the loop is placed around a pair of forceps, the tonsil is grasped by them, the loop engaged around the tonsils and tightened. The operation of removing adenoids may be performed coincidently with the tonsillotomy, as no hæmorrhage interferes with the administration of chloroform or ether; a point of no inconsiderable value.

It often happens that a moderately enlarged tonsil is quite impacted between the two pillars of the fauces. In such a case a small portion may be removed with the electro-cautery snare, which will afford a larger loss of tonsillar substance than simple cauterization.

Sequences are quite as exceptional as in other methods of tonsillotomy. In the 33 tonsil-removal operations performed last year by this method, no case presented anything beyond pain in the throat and occasionally slight pain in the ear. As is usual in most cases, a mild pharyngitis followed the operation. In one case, that of a young man of 18, otitis media followed eleven days after the operation, which was attended by no unusual symptoms, and hence, I think, not responsible for the otitis.

4. *Removal of the uvula.*—In the removal of the uvula the snare is convenient of application, the uvula being permitted to fall into the loop. The removal is soon accomplished, without any slipping, without pulling down the mucous membrane, and without more or less of the uvula removed than was intended. Of course, as in all electro-cautery snare operations, no hæmorrhage follows. The stump is more even and heals far more quickly. There is no such pain upon swallowing following this operation as after the cutting operations, and, with very few exceptions, patients were able to eat fairly well upon the day of and the day succeeding the removal, comparing very favorably to the after effects of operations performed with a knife, scissors, or uvulatome. Electro-cautery snares which have been in use are open to objections on account of their uncleanness, on account of the length of wire necessary, and because of the occasional short-circuiting of the current. It is practicably impossible to perform anything like an aseptic operation with a snare of the old make, as when used a single time the discharges so collect upon the silk and cotton insulation as to render it unfit for subsequent use. The snare, however, which I had the honor of presenting before the laryngological section of the American Medical Association in 1892, and which I have been using for two years, negatives these objections. Every portion of the instrument is separable,

the canulæ, the copper wires, the ivory tip, and the rubber insulation. It therefore may be subjected to the ordinary aseptic procedures, the rubber insulation being in this respect far superior to the silk or cotton insulation.

By means of the two stout copper wires which are made to pass through the canulæ, and which are supplied with an eyelet in the upper end, a substantial loop may be made. I have of late used steel instead of platinum wire for the reason that it is firmer and more apt to remain where placed. It is not so lasting as the platinum, yet it has never failed to act. For every operation a new piece of wire should be used, as it becomes brittle after the current has passed through it. As the eyelets are very easily rethreaded, this is not a disadvantage.

Very valid objections have been urged against batteries of all kinds, whether primary or storage, and this condition of things has had no little to do with the non-adoption of the electro-cautery snare by many practitioners. The great progress of electrical inventions has come to our relief, for we now have appliances for changing the current used for lighting purposes so that it is available for the cautery. This supplies the missing link of electro-cautery possibilities, and makes those who use the electro-cautery snare secure in feeling that they have a medium of electric cauterization that is certain. I have during the past year been using for this purpose the converter made by the A. S. Aloe Instrument Company, of St. Louis, Mo., and I can testify that it has not failed me a single time.

Finally, and in all confidence, I beg to reintroduce the three postulates of electro-cautery utility in nose and throat diseases, the three desirable ends in the removal of all non-osseous projections: (1) No hæmorrhage, (2) celerity of operation, and (3) precision.

## PROCEEDINGS.

ADDRESS BY THE PRESIDENT OF THE SECTION, C. M. HOBBY, M. D.,  
IOWA CITY, IOWA.

GENTLEMEN OF THE OTOLOGICAL SECTION: In opening this otological section of the First Pan-American Medical Congress we can congratulate ourselves that, notwithstanding untoward obstacles, accidents by field and flood, and such financial stringency as perforce in many parts of our country prevents those that would greatly enjoy participating in this congress from obtaining for use their hard-won increment, long kept for this occasion, we have gathered together in sufficient numbers to assure the permanency of the body, and from a glance behind the veil I have no hesitation in saying that the character and quality of the papers to be presented guarantee for the First Pan-American Medical Congress a higher scientific value than has heretofore been obtained by any general medical assemblage on this Western continent.

The opportunity for interchange of opinions between the North and the South, the more than 100° of latitude that separates our confrères, the plains, table-lands, and the mountains of the tropics, suggest at once a multitude of questions that we of the North look to our brethren of the South for solution; but the story of the mucous membranes is a long one, and we hope that hereafter we may frequently share in similar opportunities for comparison. Meanwhile we have assurance of the kindly help of our fellows from the denser populations of Europe; and I congratulate you upon the presence with us of one whom we all reverence as a master; for whether we have been pupils at Vienna, or have through literature gleaned the steps by which otology has advanced since the days of Toynbee, there is not one of us but who acknowledges a debt of gratitude for the landmarks established by Prof. Adam Politzer; and I think I voice the universal sentiment of felicitation that his genius is still active, and that he is here to speak for himself. I have sampled some of the good things he has brought to you, and I assure you that it will hereafter rejoice you to have been present.

I shall detain you but a short time with the topic of my address, not because I do not profoundly believe that the methods of diminution of deaf-mutism are not among the most important considerations to come before you, for I do believe that in this case prevention must take the place of cure, but because I do not desire to encumber an address necessarily statistical with a flood of details. The material I have used, with the exceptions caused by death in the last eight years, is accessible to all for verification, and the facts are presented with the desire that you criticize the conclusions.

## THE PREVENTION OF DEAF-MUTISM.

It has long seemed to me that in this era of preventive medicine, when our outer portals are so rigidly guarded against the admission of diseases like smallpox and yellow fever, which are easily recognized and quickly controlled at least in our Northern cities, that so little attention has been paid to an internal enemy whose permanency robs the State, the family, and civilization in a ten-fold ratio to the infections against which we so wisely and strenuously guard. It is an unfortunate, but undoubted fact, that census reports and governmental inspections in this country reveal only part of the truth. People feel that deformity, incompetency,

disease and the results of disease, carry with them a stain, a disgrace, and, if generally known, a discount upon the family importance which they desire to conceal. Especially is this true among the poor and uneducated, and the census enumerator does well if he gathers all the family names and ages and a small part of the truth in regard to the defective classes. In my own State, which probably contains the most prosperous agricultural population in the Union, without large cities, and with the most equal diffusion of education among all the States, I am satisfied that the census of 1880 gave less than 70 per cent of the number of blind or mute. This estimate is confirmed by Dr. Billings's comparison of the reports of deaths by the enumerators in Massachusetts and New Jersey compared with the State reports. This comparison showed that in 1880 the enumerators were deficient in Massachusetts to the extent of more than 26 per cent and in New Jersey to more than 34 per cent, and he remarked that "in no State is the deficiency in the enumerator's returns less than in Massachusetts." It is not probable that the enumerators were more accurate in regard to defective classes than they were in regard to mortality. We have no means of comparing the two enumerations for 1890, but as the ratio of 68 deaf mutes to the 100,000 population was maintained in 1890, we can say safely that the census report of 41,283 deaf mutes for 1890 represents an actual 50,000 or upward of this defective class. Taking the defective classes together we find that the proportion is as follows: Insane, 37 per cent; idiotic, 30 per cent; blind, 19 per cent; deaf-mutes, 14 per cent.

From the nature of the affliction public attention is seldom directed toward the mute. In his early years, no means of communication existing between him and the public, he is not noticed, and the lack of any external mark of his defect leaves him devoid of the sympathy that the people give to the blind. Later on, after he returns from the institution for education, he naturally fellowships with those who talk his language, and is only accidentally recognized by the public as one of the defective class. He is able to labor, to earn his own living, and usually succeeds in so doing; but without criticising the methods of instruction which are the results of the formulated experience of those who devote their lives to this noble work, with a few exceptions that surmount in an incomprehensible manner the barriers that exist, the great majority of mutes reach the age of 20, able only to converse with their fellows, and those that take the pains to acquire their language; but with such a limited range of tools of ideation as to make them unable to think or reason other than as a child of 10 or 12, or as a savage with small vocabulary, the mental action dwarfed, the enormous area of the incomprehensible that surrounds them when they reach out toward the public and converse with the slate, makes them seek their own kind for association and segregate them from the world. The mental incompetency so often manifested has in some of the States, I believe, been recognized as irresponsibility, and I believe that a large proportion of the 50,000 are as irresponsible for the results of emotional acts as are the insane or idiotic. While fostering every effort and every method that promises amelioration to this unfortunate class, I believe the duty of the medical profession goes further; that upon us rests a responsibility not met by simply using our influence to secure early training educationally, but which will only be accomplished when we shall have reduced to the minimum the number requiring such training.

Is any considerable proportion of deaf-mutism preventable? In considering how large a proportion can be so classed, we are met with a professional and popular opinion, which has so dominated the authors upon diseases of the ear that nearly all have contented themselves with accepting the statement of the teachers, that one-half of the mutes are "born deaf." A few have indicated that perhaps the proportion of congenital cases was overestimated, and it was without other preconceived opinion and against all that I had been taught that I was led,

after the examination of the admission papers of more than 1,000 cases, to go into a careful inquiry as to the basis of this general belief that at least one-half of the cases were congenitally deaf. After discovering that in former times, for educational purposes, teachers had classed all pupils that had never learned to talk as "born mute," and after finding that all cases in which the parents were unable to say when a child became deaf, or simply said, "He never seemed to understand what was said to him," that the case was almost invariably classed as congenital, I entered upon the investigation that led me to say in a paper on "Cerebro-spinal fever a cause of deafness," read before the Ninth International Medical Congress (Washington, 1887): "With a little care in sifting I have found out of 1,111 cases in Iowa only 13.3 per cent of congenital mutes, and I believe that a majority of those who have investigated the subject practically will agree that even this percentage is too large." Since that time a personal and careful examination of 250 cases, followed by correspondence, showed that only 14 per cent could have been born deaf, and the probability is strong that many of these cases have acquired the deafness in early infancy. The analogy existing between the causes of congenital deafness and pre-natal blindness would lead us to expect something like a parity in proportion; and the absence in statistics of congenital deafness of one ear points in the same direction. When we come to consider that the percentage of deaf mutes is only between 10 and 15 per cent, which is certainly true for the United States, we have left appealing to our art for relief 85 per cent of deaf mutes in whom disease of an active nature has played the devastating part in the early months and years of childhood. While simple middle-ear diseases unaccompanied by suppuration and consequent destruction of parts may produce deafness of so high a grade as to prevent the acquisition of vocal language, my examinations would limit the probability of this to less than 4 per cent. The destructive action of suppurative disease plays a more important part, reaching probably 10 per cent, and the remainder, nearly or quite 76 per cent, result from intra-cranial causes, and amongst these must be classed many attributed to scarlet fever, for less than half the cases following scarlet fever, examined by me, have shown marked lesions of the middle ear upon both sides. We hope that the diffusion of knowledge amongst general practitioners and the increased skill and thoroughness with which diseases of the nose and throat are managed by the profession at large will lead to more prompt and efficient treatment of such diseases when complicating the exanthemata, and so materially lessen destructive suppurative processes.

There still remain the great majority in whom intracranial, especially labyrinthine diseases produce deafness in the early months of life, and for whom there has seemed no hope. The study of these conditions is surrounded with great difficulty. Pathologically, the opportunity for close comparison of the clinical history with the morbid anatomy is extremely rare, and the recorded observations have hitherto given us little of value as to the relation between acute diseases and the development of extreme deafness. Clinically, we are met with the difficulty that only a small proportion of the cases are seen and studied by a medical attendant during the important period when deafness is acquired. A child of a few weeks or months is indisposed, fretful, its head is thrown back, it may decline nourishment, an eruption may, or may not exist, the symptoms pass away without any physician being called, and months may elapse before it is discovered that the child is deaf. Or the medical attendant being called, the disease recognized and recovery taking place to the gratification of the physician, the same delay exists between convalescence and the recognition of deafness; such occurrences are familiar to you all, and should lead to no censure of the attendant, for in the first place it is extremely difficult in infancy to determine whether the hearing is badly impaired or not, and we are not even certain whether the pathological cause of deafness is always or even usually developed synchronously with the acute affec-

tion causing it. The fact shown in my former paper that cerebro-spinal fever bears a causative relation to deaf-mutism, in the United States in from 30 per cent to 50 per cent of cases, is now well recognized, and while as a rule admission papers of institutions can be considered of as little except negative value, the exceptions in which the clinical history is developed by a careful medical attendant are sufficiently numerous to make certain that other febrile diseases, especially typhoid fever and mumps, are occasionally followed by deafness from internal lesion; and as indicated before, scarlet fever is a more frequent cause of internal ear deafness than of destructive middle ear disease.

Nothing in statistics or clinical history of the cases personally examined affords anything satisfactory in regard to the relationship of acute inflammations of the pia mater, "leptomeningitis infantum," "basilar meningitis," "purulent meningitis of the convexity," "traumatic meningitis," "consecutive meningitis," "metastatic meningitis," or possibly "tubercular meningitis," to lesions producing deafness; although we may believe that through these imperfectly known conditions the results are produced which are attributed to "rheumatism," "fright," "convulsions," "hydrocephalus," "colds," and the fevers generally. It is unfortunate that the term "epidemic" has been associated with cerebro-spinal fever, because on the part of the profession an erroneous idea has been developed. This disease is epidemic as typhoid fever is epidemic, under special circumstances, but like typhoid it is constantly endemic in all parts of the United States. Its prevalence as a scourge in special localities, and the undoubted fact that in malarial portions of the country many cases of cerebro-spinal fever were supposed to be remittent and other fevers, led to failure to appreciate this endemic character. However, it is in evidence that in Michigan there were reported, in 1873, 812 deaths, and in the ten years following a mean mortality from this cause of 178 per annum, the greatest number 330, the least 101, in a single year, and these cases scattered through the various counties and distributed through the twelve months so uniformly as to show conclusively for this State that the cases could all be considered sporadic. The same evidence is furnished wherever vital statistics are published in America. The occasional occurrence of epidemics in restricted localities among men and animals does not lessen the importance of the fact that this disease is always with us. Another important fact in this connection is developed by study of the census reports of 1880 and 1890, namely, that there exists a remarkable uniformity in the proportion of deaf-mutes to the total population North and South, East and West, through all the diversities of climate and elevation of this great country, and that the proportion remains nearly the same in the white and colored races; also that while scarlet fever produces its greatest ravages in the densely populated portions of the country and almost disappears as a causative agent in the production of deaf mutism in some of the States of the Mississippi Valley, we find cerebro-spinal fever producing an almost uniform rate of mortality in all parts of the country.

In thus presenting the conditions that must be met in efforts at prevention of the deafness of childhood, I wish to reiterate that the conclusions presented in the foregoing, differing in many respects from the accepted doctrines, have been arrived at only after careful clinical study of this helpless class, and I am sure the personal study of these cases in the institutions for education and careful sifting of the clinical histories of patients, with the assistance of those familiar with the incidents of early childhood of the victims, will lead to similar conclusions in any of the United States. Inherited syphilis, which had sparingly marked the features and teeth of those examined by me, will doubtless in institutions drawing from large cities appear more frequently, and the same is probably true of the effects of suppurative process, but I believe not to an extent to produce material change in the statistics of causation. It is apparent, therefore, that any considerable suc-

cess in diminishing the frequency of mutism must have its origin in the study of intra cranial diseases; the specific cause of cerebro-spinal fever remains to be discovered, and with a knowledge of the methods of infection and the reasons for its extensive dissemination the physician will be better prepared to study its natural history. To accomplish this desirable end it is necessary that the attention of the profession at large, the general practitioners of the whole country, be called to the frequency with which deafness follows apparently slight ailments of children, and impress strongly upon their minds further the fact that destruction of hearing most frequently takes place without symptoms referable to the ear. Through the public institutions a more accurate history of each individual could be obtained by correspondence with parents and medical attendants. The amount of energy that has been wasted in the endeavor to prove that deaf-mutism is largely the result of consanguineous marriages would be sufficient to greatly enlarge our knowledge as to the beginning of deaf-mutism. Public institutions can more readily than medical societies appeal to the public for coöperation, and through the public press awaken the people to one of the neglected results of infantile disease.

I am aware that much that I have said is an old story to most of you, but the strong impression made upon my mind by the conflict between the methods of causation as described in literature and the history of the cases studied in institutions, and the neglect of writers upon general medicine to afford to the general practitioner due warning of the dangers of the minor as well as the graver cerebral lesions, must be my excuse for appealing to you to investigate for yourselves these important questions, and I feel deeply grateful that I am enabled to make this appeal to those interested in the diseases of the ear from so many lands, representing all habitable latitudes.

## PAPERS READ BEFORE THE SECTION.

---

### OTACOUSTIC TREATMENT; ITS HISTORY AND RESULTS UPON THE DEAF AND DEAF MUTES.

By J. A. MALONEY, M. D., of Washington, D. C.

Prior to the year 1886 I devoted a great deal of time to experiment in physics and principally to its branch acoustics; the result of which was the development of the instrument since known as the otophone, which differed in construction from anything previously used for the purpose. It had three chief characteristics: (1) It did not enter the meatus auditorius externus; (2) it was a tube closed at one end by a flexible membrane, and thereby confined a column of air; (3) it was free from reverberation so common to the old forms. Its advantages reached the ears of Drs. S. Wier Mitchell and C. H. Burnett, of Philadelphia, and through them I was requested by the College of Physicians of that city to lay the matter before them and demonstrate its advantages. This was done on April 6, 1887. (See Transactions of the College of Physicians, third series, Vol. ix, Philadelphia, 1887.) Subsequently I was invited to make tests upon deaf mutes at the Pennsylvania Institution for the Deaf and Dumb and a confirmatory test at the National Deaf Mute College, Washington, D. C., and the results were laid before the American Otological Society, July 19, 1887, New London, Conn. (See Transactions American Otological Society, Vol. iv, Part I.) The cases so tested were classified as follows; (1) Five congenital cases; (2) five who lost hearing between the ages of 1 and 5; (3) five cases of profound hardness of hearing, being

educated as mutes, but who hear a little, can talk and understand lip reading, and may be termed "semi-mutes."

After the tests in Philadelphia (the first made), Dr. Burnett expressed surprise at the demonstration of the hearing power in the five congenitals. The results attending these experiments suggested the thought of a new field of treatment in chronic deafness, by means of passive motion, and I turned to physiological acoustics for light and knowledge, but found the path had been traversed only partially, until the portals of this domain of science had been opened by Weber, Lucac, Hemholtz, Politzer, Rieman, Henke, and in our own country by Blake, Burnett, and Sexton, and the literature upon the subject was sparse and not specialized. Up to this time otology depended upon local applications and "Politzer inflation." Then came Siegel's otoscope, as a means of passive motion, and later Delstanche's modification of same, but success in their use was rare, why? Because it produced a too violent and anti-periodic motion, and the ear of the lower as well as the higher order of animal shrinks from the same.

As before stated, prior to my discovery local treatment and Politzer inflation were the means most relied upon for success. The aurist in addressing himself to the external canal had light before him, as far as it related to that part. With Politzer inflation he could render the Eustachian tubes more patulous, and by so doing admit more air to the middle ear in an endeavor to bring about that important factor of audition, i. e., equalization of pressure upon each side of the membrana tympani; but should he succeed in getting a normal lumen established, any fixation of the transmitting mechanism prevented further success. This was the status of treatment in chronic deafness up to the year 1888, when I announced the discovery that sound, arbitrarily applied to meet conditions of each case, was a therapeutic agent of importance in chronic deafness.

The indications for scientific passive motion had long been suggested by the well known phenomenon of "paracusis Willisiana." Hearing better in a noise is an acuteness of audition made so by motion, but entirely different from the natural method for the following reason: Hearing better in a noise is a distinct function from that of normal hearing in that there is an antecedent momentum established by the noise through mass vibration, especially in a moving vehicle, and the voice as a superimposed vibration retards or interferes with the existing vibrations. This interference addresses itself to the sensorum as sound. In the normal ear the membrana tympani and ossicula auditus or transmitting mechanism has a direct action in the translation. Having completed the method and means for a system of aural massage, I designated it "otacoustic treatment," which covered in its meaning any sound to the ear. In my earlier cases I was struck by the relief afforded as well as the cessation of tinnitus aurium in many cases, and upon reflection I turned to my notes of experimentation, in which I tried to produce those sounds mechanically which are set out in my article "The sphenoid bone; some of its possible functions," (see New York Medical Journal, August 11, 1888). In speaking of tinnitus aurium, I said:

I would here state that I have produced the singing sounds by getting a very loose contact in a Blake telephone transmitter, the contacts of which would be for the purpose analogous to the articulations of the malleus and incus, from which I have concluded that singing sounds are due to slight disarticulation of the malleo-incudal joint placed in vibration by some subjective cause, and continued by reason of the membrana tympani acting as a retractile spring, thus producing the same effect as the "Neff hammer" or make-and-break device upon the induction coil.

Much time was required in formulating the method of treatment in individual as well as classified cases during the first two years, the work being empirical because I had no rule of procedure based upon an experience by others for my guidance. That partial ankylosis or fixation of the ossicula auditus could be relaxed by this form of passive motion was accepted by some of the most eminent

otologists of our day, and I was encouraged by them to persevere. There were some, however, who ascribed my success to education of the perceptive tract, and this alone.

In the year 1890 I treated a patient, who was then dean of the Southern Homœopathic Medical College at Baltimore, Md. At the time of visit he was accompanied by a Dr. H. F. Garey, professor of otology in said college. Some time after this visit I understood that said Garey had applied the doctrine of "*similia similibus curantur*" to sound as a therapeutic agent, or, in other words, that the similar sound of tinnitus applied would cure the tinnitus as well as the deafness. Later on I was astonished to find in the lay press such announcements as "New way to cure deafness," "Deaf hear by phonograph, by Dr. H. F. Garey," "Sound waves in the treatment of aural diseases, by Dr. H. F. Garey." Whereupon I sent a protest to the faculty of said college against the unfair assumption upon the part of Garey; they in response indorsed his action.

This party used the phonograph and the similar sound (being a homœopath) as the tinnitus, but has since abandoned said instrument, as I did in my early experiments years ago. Others have since suggested the use of the telephone, but the use of phonograph and telephone for commercial purposes has produced ear troubles, in the latter case known as "telephone ear." They are frequently met with by otologists of our large cities. "Telephone ear" was first pointed out by Dr. Clarence J. Blake, before and during the year 1888 (see Transactions American Otological Society, Vol. ix, part 2, 1888) and later by M. Gelle abroad.

No man has used the phonograph more, nor had a greater opportunity of testing its efficiency in deafness than its inventor, Thomas A Edison, yet he has suffered for years from progressive deafness, and I was informed lately that he is profoundly deaf. The reason for the deleterious effect upon the ear from the use of these instrumentalities is the shock necessarily created by their sound-producing mechanism.

The method and means which I employ in otacoustic treatment are: (1) The tube or otophone hereinbefore mentioned closed at one end by a flexible membrane, and confining a column of air; (2) the method, which consists in the use of articulate sounds (preferably) by reading, twice or thrice daily for a given length of time, according to conditions of case; power of voice also being regulated.

Such is the history of sound in its application to otology up to this time. The diagnosis in profound deafness requires a knowledge of the history in each case and experience in the application of this method of treatment, based upon a familiarity with physiological acoustics. Strange as it may seem, otology, as taught to-day, ignores physiological acoustics, which, to my mind, is a *sine qua non* to that special branch of medicine and surgery.

I will now call your attention to the class of cases and degree of success obtained by otacoustic treatment:

*Case 1.*—Dr. B., a busy practitioner of this city, had three or four years previous, by diagnosis, Menière's disease. He applied to me for test May 4, 1887. Right ear only involved. He was very much surprised at being able to hear on that side. The next day I received a message, asking me to call at his office and repeat the test. After making the second test he apologized for being skeptical, and said that three of the most eminent otologists abroad had made an unfavorable prognosis in his case. The following day he commenced treatment, and on July 12 (two months afterwards) could hear unaided voice in a conversational tone a distance of 15 feet. He asked at this time what he could do to acknowledge the result, when I suggested that he communicate the facts to Dr. C. H. Burnett, of Philadelphia, which he did in a letter which was read at meeting of American Otological Society, New London, Conn., July 19, 1887.

*Case 2.*—Ralph G., æt. 12; February 12, 1887; diphtheria at 6 years. Before visit to me the boy had been treated in this country and abroad. R. E., destruction of membrana tympani, save a portion of membrana flaccida; ossicles absent; L. E., otitis purulenta; exacerbations frequent from exposure; pain relieved by discharge; membrana tympani perforated and sclerotic; inflammation with sup-

puration frequently recurring; slight naso-pharyngeal catarrh; excessive hypertrophy of tonsils (almost touching each other); loud voice; L. E. = 2 inches, R. E. = 0. Diagnosis had been made of paralysis of auditory nerve. The boy was an expert lip reader, and had the "deaf face" well developed. After examination I found after a five-minute test that he could hear, R. E., moderate tone at meatus, and range extended to 12 inches for L. E. I made a favorable prognosis for development of hearing to serve practical purposes through life. The usual local applications were used upon ears; naso-pharynx and tonsils and otacoustic treatment faithfully followed. On May 20, 1889 (a little over three months), the hearing power had been brought up as follows: With eyes closed could hear ordinary conversation at 12 feet, and this remained fixed up to time of last visit, August, 1889, his mother having removed to the far West; the deaf face had disappeared; he was ruddy and robust, and I think it would have puzzled an expert to discover that the boy had ever been profoundly deaf.

*Case 3.*—Mrs. W. H. H., æt. 46; June 1, 1889; atrophic nasal catarrh; R. E. deaf for fifteen years. W., R. E. = C., L. E. =  $\frac{6}{60}$ ; B. C., good; M. T., sclerotic, opaque, retracted; tinnitus very persistent and varying; E. T. partly patulous. Patient was very skeptical of prognosis made after examination and tests, but her husband, who was present, urged her to proceed with treatment, which she reluctantly did. After thirty days the following results were shown: W., R. E. =  $\frac{9}{60}$ ; L. E.,  $\frac{30}{60}$ . Ordinary conversation heard in any part of room with back to speaker; tinnitus very much reduced. This patient was a neurotic and at the menopause. In November, 1890, she called to inform me that she had been ill with typhoid fever, but her hearing remained good. At this time tests showed: W., L. E. =  $\frac{45}{60}$ , R. E. =  $\frac{16}{60}$ ; tinnitus scarcely perceptible, and then only at times.

*Case 4.*—February 15, 1889, Mr. J. Van S., æt. 36; lip reader; atrophic nasal catarrh. This case was sent by specialist, who was treating him for otorrhœa. Deaf R. E. three years, L. E. twenty-five years; had been under treatment for some years; W., R. E. =  $\frac{1}{60}$ , L. E. = C.; V., R. E. = 3 feet, L. E. meatus. After four months conditions were W., R. E. =  $\frac{20}{60}$ , L. E. =  $\frac{6}{60}$ ; conversational tone of voice heard in any part of room (15 by 15) and low voice at 3 feet with L. E. The deaf face in this case was pronounced at time of first visit. On May 19 patient presented an improved appearance, no deaf face, and was bright and cheerful; V., undertone, 15 feet; W., R. E. =  $\frac{40}{60}$ , L. E. =  $\frac{16}{60}$ . On May 19 patient presented an improved appearance, no deaf face, a bright and cheerful countenance; V. = moderate, 15 feet; W., L. E. =  $\frac{16}{60}$ , R. E. =  $\frac{40}{60}$ .

*Case 5.*—Miss A. De L., æt. 24; January 16, 1890; expert lip reader; post-scarlatinal deafness since early childhood; R. E., W. =  $\frac{0}{60}$ , L. E., W. =  $\frac{2}{60}$ ; B. C. good; chronic muco-purulent discharge from L. E.; M. T., R. E., opaque, retracted, and full of cicatrices, L. E., perforation in inferior posterior, quadrant and tissue bathed in muco-purulent secretion; E. T., R. closed, L. patulous; treatment for discharge of L. was carried out under otologist who sent the case. I directed otacoustic treatment to development of hearing in R. E. with disuse of L. E. because of sensitiveness (closing meatus with wool) for L. during medication. At end of thirty days, otacoustic treatment was used on both sides, the purulent discharge from L. having subsided. On May 8, 1890, conditions were, W., R. E. =  $\frac{8}{60}$ , L. E. =  $\frac{25}{60}$ . October 1, 1891, W., R. E. =  $\frac{25}{60}$ , L. E. =  $\frac{26}{60}$ .

*Case 6.*—Mrs. E. R., æt. 38; September 30, 1890, chronic naso-pharyngeal catarrh; M. T., L. E. opaque, thickened, retracted; E. T. partly patulous; M. T., R. E. opaque upon posterior segment, retracted; tinnitus aurium both sides; unfavorable prognosis by several specialists; had been under treatment for years; W., R. E. =  $\frac{6}{60}$ , L. E. = 0; B. C. good; V., R. E., loud = 6 feet, L. E., loud = meatus. October 30, tinnitus, R. E. seldom noticed, L. E. very much reduced; V., R. E. 10 feet, L. E. 10 inches. December 15 W., R. E. =  $\frac{6}{60}$ , L. E. =  $\frac{4}{60}$ ; V., R. E., conversational tone, 15 feet, L. E., conversational tone, 4 feet. January 22, 1891, no tinnitus; W., R. E. =  $\frac{8}{60}$ , L. E. =  $\frac{6}{60}$ . May 4, R. E. =  $\frac{10}{60}$ , L. E. =  $\frac{9}{60}$ ; V., conversational tone, R. E. 20 feet, L. E. 10 feet; no tinnitus. Upon first visit this patient stated "the deafness is of minor importance compared to the suffering endured from the tinnitus, and will be happy if rid of it within two years."

*Case 7.*—Mrs. G. B. This case was sent by specialist in another city, August 23, 1890; W., R. E. =  $\frac{8}{60}$ , L. E. = C. He reported under different dates as follows: November 19, 1890, "I have seen Mrs. B. but three times since she commenced your treatment. On November 13, she heard W., R. E. = 24 inches, L. E. = 4 inches; compared with R. E. 18 inches, L. E. =  $\frac{1}{2}$  inch. October last, she is delighted, so am I." On February 20, 1891, she again reported, W., R. E. = 26 inches, L. E. = 12 inches.

*Case 8.*—Mrs. M. H., æt. 40; May 4, 1891; hypertrophic nasal catarrh; R. E., deaf six months, L. E., deaf eight years; M. T., R. slightly retracted, luster and trans-

parency somewhat diminished; L. retracted opaque; W., R. E. = C., L. E. = O; V. moderate, R. E. = 6 feet, L. E. = O; no perception of quality, as patient expressed it, every sound was "whiz, whiz." June 2, W., R. E. =  $\frac{4}{60}$ , L. E. =  $\frac{1}{60}$ ; V. mod., R. E. 10 feet, L. E. 4 feet. June 26, W., R. E. =  $\frac{14}{60}$ , L. E. =  $\frac{10}{60}$ ; V. mod., R. E. = 14 feet, L. E. = 10 feet. October 10, W., R. E. =  $\frac{24}{60}$ , L. E. =  $\frac{15}{60}$ ; V. mod., R. E. = 20 feet, L. E. = 17 feet.

*Case 9.*—Mr. W. G. P., æt. 25; November 27, 1891; atrophic nasal catarrh; lip reader; M. T., R. E. = perforated, retracted, opaque, L. E., retracted, opaque, E. L., R. closed, L. partly patulous; W., R. E. =  $\frac{1}{60}$ , L. E. =  $\frac{2}{60}$ ; V. Loud, R. E. = 12 inches, L. E. = 30 inches. December 24, W., R. E. =  $\frac{14}{60}$ , L. E. =  $\frac{20}{60}$ ; V. mod., R. E. = 6 feet, L. E. = 8 feet. January 21, W., R. E. =  $\frac{24}{60}$ , L. E. =  $\frac{24}{60}$ ; V. low, R. E. = 10 feet, L. E. 10 feet. March 2, W., R. E. =  $\frac{30}{60}$ , L. E. =  $\frac{30}{60}$ ; V. mod., R. E. 16 feet, L. E. 13 feet. April 22, W., R. E. =  $\frac{34}{60}$ , L. E. =  $\frac{32}{60}$ ; V., R. E. = 18 feet, L. E. = 16 feet. This case was treated otherwise by aurist who sent case to me.

*Case 10.*—Miss H. R. B., æt. 28; January 4, 1892; lip reader; atrophic nasal catarrh, tinnitus aurium; M. T., R. E. retracted, L. E. retracted, opaque; E. T., R. patulous, L. partly patulous; W., R. E. =  $\frac{3}{60}$ , L. E. =  $\frac{15}{60}$ ; V., R. E. 16 inches, L. E. 3 inches mod. February 14, W., R. E. =  $\frac{14}{60}$ , L. E. =  $\frac{4}{60}$ ; V. mod., R. E. 5 feet, L. E. 2 feet. April 5, W., R. E. =  $\frac{16}{60}$ , L. E. =  $\frac{6}{60}$ ; V. mod., R. E. 12 feet, L. E. 6 feet. May 7, W., R. E. =  $\frac{24}{60}$ , L. E. =  $\frac{15}{60}$ ; V. mod., R. E. = 26 feet, L. E. 20 feet; no tinnitus except slightly at period.

*Case 11.*—Miss K. M., æt. 32; February 18, 1892; atrophic nasal catarrh; M. T., R. E. retracted, cicatrix, opaque, L. E. retracted; E. T. partly patulous; W., R. E. =  $\frac{2}{60}$ , L. E. =  $\frac{20}{60}$ ; V. mod., R. E. 24 inches, L. E. 4 feet. March 28, W., R. E. =  $\frac{10}{60}$ , L. E. =  $\frac{24}{60}$ ; V. mod., R. E. = 12 feet, L. E. 20 feet. May 9, W., R. E. =  $\frac{26}{60}$ , L. E. =  $\frac{58}{60}$ ; V. mod., 15 feet, L. E. 30 feet.

*Case 12.*—Miss M. R., æt. 15; March 4, 1892; scarlatinal deafness; R. E. only; had been under treatment for years; W., R. E. =  $\frac{3}{60}$ ; V., R. E. 12 inches, moderate; M. T., opaque, retracted; E. T., patulous. May 27, W., R. E. =  $\frac{45}{60}$ ; V., R. E. 12 feet, moderate. June 15, W., R. E. =  $\frac{52}{60}$ ; V., R. E. 21 feet, moderate.

*Case 13.*—Mr. L. S., æt. 68; March 14, 1892; chronic atrophic catarrh; M. T., K. E., retracted, opaque, calcarious deposits, L. E. retracted, opaque deposits; E. T., partly patulous; V., R. E. = 12 inches, L. E. = 24 inches; W., R. E. =  $\frac{0}{60}$ , L. E. =  $\frac{0}{60}$ . April 27, W., R. E. =  $\frac{4}{60}$ , L. E. =  $\frac{12}{60}$ ; V., R. E. = 7 feet, L. E. 13 feet, moderate. May 27, W., R. E. =  $\frac{10}{60}$ , L. E. =  $\frac{25}{60}$ ; V., R. E. = 9 feet, L. E. 21 feet, moderate.

*Case 14.*—Katie J., æt. 8; June 1, 1889; scarlatina at 2 years; a good lip reader for one so young; profoundly deaf; no supposed hearing; articulation bad; M. T., R. retracted, parchment-like in appearance; L. better appearance; E. T., R. slightly patulous; L. patulous; diagnosis by several specialists paralysis of auditory nerve; after test, V. loud, R. E. = 0, V. loud, L. E. = 1 inch. As this was an out-of-town case the mother wrote after six months as follows: "I find it has been the means of great improvement in hearing and articulation." The father writing later to the physician who sent the case to me said: "We feel satisfied there is a marked improvement in her hearing; she now hears with both ears; she frequently asks, 'Which is my good ear?'"

*Case 15.*—Noma S., æt. 6; July 19, 1890; scarlatina at 5 years; W., R. E. =  $\frac{0}{60}$ , L. E. =  $\frac{0}{60}$ ; V., R. E. loud, 5 feet; B. C. good; L. E. loud, 2 feet. September 16, 1890, W., R. E. =  $\frac{10}{60}$ , L. E. =  $\frac{6}{60}$ ; V., R. E. 18 feet, moderate tone, L. E. 10 feet, moderate.

*Case 16.*—Miss C. P., æt. 22; February 12, 1889; supposed congenital; sent by a New York specialist for determination of hearing power. Had been educated as a deaf mute by the Bell visible-speech method. Upon examination I found hearing upon both sides, and after ten minutes she could repeat the test words naturally, conversation upon her part, owing to system of education, being in a monotone. For prognosis I gave improvement in audition sufficient for articulation. I heard nothing from this case until five months had elapsed, when the following report was sent from the person carrying out my instructions: "In less than a month 74 words and 40 sentences had been learned and were recognized upon day of review (end of month). At end of fifth month she had learned and could repeat many other words, besides figures up to 100." A physician residing in the city, becoming interested in the case, requested a test in his presence. He selected figures up to 100 as test. The teacher then selecting figures here and there within this limit called them to her and they were repeated without a mistake. Her mother could at this time, with unaided voice, pronounce a word close to meatus and her daughter would repeat it. This was the first time she ever heard her mother's voice. I have heard nothing from this case since directly, but understand it was laid before the American Association to Promote Teaching of Speech to the Deaf in New York, 1890. It was again referred to by the secretary of the said

association in an invitation for me to deliver a lecture before that body upon the cultivation of hearing at their June meeting, Lake George, N. Y., 1891. Said invitation I was forced to decline, owing to affliction in my family at that time.

*Case 18.*—Bessie B., æt. 16; January 10, 1891; scarlatina at 2 years. Her mother stated that an unfavorable prognosis had been made by several specialists. Owing to her mental condition she was at this time an inmate of an institution for feeble-minded children at Font Hill, near Ellicott City, Md. While conversing with the mother the girl sat looking at the ceiling, talking to herself and twirling her thumbs. She was very submissive to all tests, but would not allow examination by aural speculum, and never would. I found hearing upon both sides, and with fork test I found conduction *per aerial* and bone. F. C., *aerial*, R. E. 2''<sup>h</sup> 3''<sup>l</sup>, L. E. 2''<sup>h</sup> 3''<sup>l</sup>; V., R. E. 2 inches, L. E. 0 loud. I made prognosis for improvement of hearing sufficient to improve articulation if she was removed from her environment and taught at home.

Upon consultation with the father, subsequently, she was placed under my care. On February 21 the mother reported that her daughter called her attention to the blowing of a distant steam whistle while on the street. March 30 F. C., *aerial*, R. E. = 11''<sup>h</sup> 12''<sup>l</sup>, L. E. = 10''<sup>h</sup> 12''<sup>l</sup>; V., R. E. = 4 feet, L. E. = 2 feet.

Articulation much improved. Patient now left the city with her mother, and under date of July 28, 1891, the latter wrote: "Her health has very much improved, and the general comment of friends is that she has improved in hearing and speaking. I teach her regularly." November 12, 1892: "She has improved in articulation, and is being educated." At this date the hearing power was V., R. E. = 6 feet, L. E. = 4 feet. I submit the foregoing cases as typical to show what can be done in many cases of profound deafness without the radical operation now so much in vogue.

#### DISCUSSION.

Dr. J. MOUNT BLEYER, New York. The phonograph undoubtedly can be used for the purpose of testing deafness as well as of curing such a malady. The trouble lies not in the phonograph but in the method of handling such an important technical instrument. Otacoustic method of treatment of deafness is the proper and only method of testing and aiding the treatment. Phonograms should be made in different acoustic grades. Tests by means of the phonograph are most reliable tests.

Prof. POLITZER. Might I ask Dr. Maloney if he uses inflation with catheter in his cases?

Dr. MALONEY. I will state that I am in the habit of using inflation after Prof. Politzer's method, and that I use the catheter only when absolutely necessary.

Dr. H. B. YOUNG, Burlington, Iowa. Briefly I wish to add my indorsement to the views expressed by the president in his address. This has recently been added to by a consultation (case cited) in which an unrecognized sporadic cerebro-spinal fever in early infancy was undoubtedly the cause of the deaf-mutism found. The importance of bringing this matter to the consideration of general practitioners can not be overestimated as a prevention of deaf-mutism.

Dr. S. S. BISHOP, Chicago. The showing made by Dr. Maloney is certainly a very favorable one. Respecting the use of the telephone and phonograph, I have never seen any good results to the hearing from their employment, while I have observed many cases of diseases of the ear apparently attributable to the use of the telephone. No cases of diseases of the ear resulting from the use of the phonograph have come under my treatment; but I do not believe it is in any way beneficial to hearing. In my clinics at the Illinois Charitable Eye and Ear Infirmary, Chicago, as well as in private practice, I have seen chronic non-suppurative inflammation of the middle ear, chronic suppurative inflammation of the same part, and ulceration of the auricle in persons who constantly use the telephone, either in the telephone-offices or in large commercial houses, that I had every reason to believe were due to the irritating effects of the constant use of the telephone. However, I am not prepared to say that this instrument will cause ear disease in

those who are not predisposed to such trouble, or who have no preëxisting affection of the ear. The gentleman who was for a number of years superintendent of the Chicago Telephone Company, and whose hearing seemed to be normal, assured me that although he was in the habit of conversing many times a day by telephone no unpleasant results were experienced. I have also questioned quite a large number of people who constantly use the telephone, and who assure me that it produces no bad effect in their cases. But I believe its use by persons whose ears are diseased is positively injurious. The injury following its use may be due to the present imperfections in its construction which allow of the whirring and crackling noises that are irritating in character. If the uses of such instruments were beneficial to hearing, why should people become progressively deaf who are constantly subjected to the action of sound waves? They do nothing more than conduct sound waves to the ear. Notwithstanding the skepticism contained in this question, I shall give this instrument a fair trial if an opportunity is afforded.

Dr. MALONEY. In reply to Dr. Bishop's remark that he did not see why persons should become progressively deaf while sound waves were constantly making impact upon the membrana tympani, it is clear to me why sound waves from unaided voice do not exert a beneficial influence in progressive deafness, because under conditions usually found in progressive deafness there is a resistance to transmission by ossicula auditus.

---

#### PATHOLOGICAL CONDITIONS FOLLOWING PIERCING OF THE LOBULES OF THE EAR.

By MAX THORNER, A. M., M. D.,

*Professor of Clinical Laryngology and Otology, Cincinnati College of Medicine and Surgery  
Laryngologist and Aurist, Jewish Hospital; Consulting Laryngologist and Rhinologist, Ophthalmic Hospital, Cincinnati, Ohio.*

The custom of piercing the lobules of the ear dates from the remotest historical antiquity, being first mentioned in the book of Genesis. It was practiced by the people of the Orient and by those of the West, and was transmitted from the races of classic antiquity through the middle ages down to our present times. Earrings were held among certain nations in high repute as talismans or amulets. They were, and I believe are still, superstitiously valued as remedies for eye affections. But their principal use was at all times, and certainly is now, that of ornaments to be worn, generally by women. And thus it happens that mothers, who who would otherwise protect their little ones from every harm and pain, will not shrink from subjecting them to an unnecessary, inexcusable, and painful procedure only to adorn them with the coveted jewel. This explains why such a barbaric custom as that of piercing the ears could have survived to our present times. It is, however, barbaric, not only because of its origin, nor on account of the crude methods by which it is practiced, but more so for the reason that not rarely more or less troublesome, and even fatal, consequences have been observed after this procedure. It is my pleasure to report to you to-day a number of such sequelæ of piercing the lobes, some of which seemed to me to be of more than ordinary interest, although there are scattered in literature a goodly number of interesting cases. Before reporting my own it may be opportune to mention a few of the observations made by others.

Hufeland saw a child die of trismus following piercing of the lobule of the ear.<sup>1</sup> Severe inflammation of the lobe, erysipelas of the ear, large granulations around the wound, cutting of the ring through the lobule, and hypertrophic thick scars

---

<sup>1</sup> Cited from Dieffenbach, *Die operative Chirurgie*, Vol. II, p. 78. 1848.

are some of the possible sequelæ mentioned by Dieffenbach.<sup>1</sup> Fibroids (keloids) have been observed by many authors and are mentioned by Knapp, Agnew, Turnbull, Finley, Bürkner, Schwartz, Politzer, Bacon, and others. They occur up to the size of chicken eggs, and are said to be more common among the colored than the white race. Politzer says<sup>2</sup> they are benign, no recurrence taking place after total extirpation. He refers, however, to the case of Agnew,<sup>3</sup> in which a tumor originating in a traumatic scar returned again and again. And, according to some observers, recurrence of these tumors is not at all uncommon. Knapp has called special attention to the fact that they are liable to recur, and that by frequent recurrence they may become malignant.<sup>4</sup> And in all cases of tumors of the auricle to be reported in this paper recurrence has taken place several times. Sexton<sup>5</sup> speaks of a cleft lobule from earrings, and saw even a portion of the lobule slough off. Kirchner<sup>6</sup> says that the lobule is not infrequently the seat of an eczema, originating by preference in the pierced holes. Altschul has reported a death from gangrene following piercing the lobes in a girl of 9 months;<sup>7</sup> and erysipelas, sometimes fatal, is mentioned recently by Haug<sup>8</sup> as being occasionally caused by the reprehensible practice of piercing the lobule.

It would be easy to multiply these cases, but these will be sufficient to show that there are abundant observations on record to make one reflect why the voices of physicians or at least of otologists are not raised against this "truly barbarous custom," as Roosa calls it. The following cases have come under my observation:

#### ERYSIPELAS OF THE AURICLE AND FACE.

*Case 1.*—The lobule was pierced in a child 2 years old, and this was followed by a severe attack of erysipelas, involving the whole auricle, auditory canal, and part of the neck.

*Case 2.*—A lady 20 years of age, who had not worn ear-rings for some time, was, on attempting to do so again, obliged to use some force in placing them. Pain, redness, and swelling soon developed in one ear, and the erysipelatos inflammation also involved face and scalp.

*Case 3.*—Also in an adult, and very similar to case 2. In this case the general symptoms were very severe, and the erysipelas, after having spread over the face and neck, invaded the pharynx. The patient recovered.

#### DEFORMITIES.

Two cases of cleft lobule were seen, caused by the ear-rings cutting through the lobe. In the one case both lobules were torn. The clefts were readily repaired by the operation advocated by Knapp,<sup>9</sup> by paring the edges and stitching the little flap left on the posterior lip over the corresponding portion of the anterior lip, thus avoiding a notch in the lobule. The result of the operation was good. The other case of cleft lobe was peculiar. It was that of a middle-aged woman, in whom the earring had torn through the left lobule about ten years ago. Two years later she got tired of wearing but one earring, and she had the left lobule again pierced close to the old aperture. In the course of time this ring had also torn through, parallel to the old slit, and the woman had now a lobule consisting of three pendants. The narrow central strip was removed, and the edges of the remaining parts united in the above-described manner. The cosmetic effect was good.

<sup>3</sup> Trans. Amer. Otol. Soc. 1882, p. 720.

<sup>4</sup> Quoted by E. B. Dench, in Burnett's System of Diseases of the Ear, Nose, and Throat. Phila., 1893, Vol. I, p. 157.

<sup>5</sup> The Ear and its Diseases. N. Y., 1888, p. 112.

<sup>6</sup> Schwartz's Handb. d. Ohrenheilk. 1893, Vol. II, p. 18.

<sup>7</sup> Ibid.

<sup>8</sup> Arch. f. Ohrenhkl. Bd. 35, p. 142.

<sup>9</sup> Archiv. of Ophth. and Otol., Vol. III, No. 1.

One case of enlargement of the opening made for earrings presented a peculiar and even ridiculous appearance. The hole on one side had gradually enlarged, from the weight of the ring, to the size of a lead pencil, and repair was desired by the patient, a young lady of 19 years, for cosmetic purposes. The edges were pared with a cataract knife, united by one suture, and healed readily. (A similar case is described by Rcosa.<sup>1</sup>)

#### ECZEMA OF THE AURICLE.

This has been observed in a number of cases to be caused by the wearing of earrings, especially when they had accidentally caused small tears of the cutis, and also after forcible placing of earrings, when the opening had been closed for some time. It was generally the acute form which was seen, causing swelling, excoriation, formation of unsightly crusts, and bleeding, often upon the slightest touch. This form is, as a rule, very painful. Removal of the cause, and treatment with ointments (for instance the Ung. Diachylon) were sufficient to produce a speedy cure. In two cases the eczema had reached the chronic stage, in one involving the larger part of the auricle, and more especially the furrow along the insertion of the auricle. These cases were more obstinate, but yielded also finally to treatment.

#### TUMORS OF THE AURICLE.

*Case 1. Fibroma (fibro-chondroma) of auricle.*—The patient, referred to me in August, 1887, by Dr. Wright, was an unmarried lady, 32 years of age, white. Had been troubled as a child with painful swellings of both lobules, which caused her to discontinue wearing earrings at the age of 17. At the age of 22 she noticed that the old swelling in the right lobule, which had been pierced higher than is the custom, and very close to the antitragus, began to grow, until it had reached the size of a small cherry. Two years thereafter it was removed, but showed signs of recurrence within a year. Three years ago, and five years after the first operation, it was again removed, but began soon to reappear, until it had reached the size of a small chestnut, involving the whole lobus. Removal was effected by a V-shaped excision, and the edges brought together by sutures. The tumor had not returned two years after the operation, the last time I saw the patient. The microscope showed, within a dense connective tissue formation, the structural elements of cartilage sparingly interspersed. A case of fibro-chondroma of this region has also been reported by Strawbridge.<sup>2</sup> The appearance of cartilage in a tumor of the lobule finds its explanation in the fact that the lobule is not entirely free of cartilage. There is, as W. His<sup>3</sup> has shown, an unciform strip of cartilage below the antitragus called *lingua auriculæ*, which is the cartilaginous support of the lobule of the auricle.

*Case 2. Fibroma of the auricle.*—For the history of the following interesting case and the specimen I herewith present to you, I am indebted to my friend, Dr. O. Landman, of Toledo, Ohio. Mrs. C. E. J., white, æt. 35. When 15 years old her earrings were caught on a pillow and both forcibly torn out. The wound healed, but later on a "lump began to grow" on both lobules. Two years afterwards both lobules were partially amputated. The left tumor has never returned. The tumor in the right ear returned six times, and reached an operable size about every three years. There were six operations after the first. Two years ago Dr. Landman saw the case for the first time, when the tumor had reached the size of an English walnut, involving the larger part of the auricle. He operated by amputating the entire auricle. About eight weeks ago the lady was seen again. There were at that time no signs of recurrence. The microscopic examination showed the tumor to be a characteristic fibroma, containing possibly a little more yellow elastic tissue than is usual in this kind of tumors, but which might be expected from the structures involved.

*Case 3. Keloid of the auricle and face.*—Miss E. P. H., of Indiana, white, 35 years old, was seen one year ago. When 18 years old a small nodule developed in the right lobule, close to the puncture. This began to grow, was painful, and was excised. Within the following seventeen years the recurrence of this tumor was

<sup>1</sup> A Practical Treatise on the Diseases of the Ear. New York, seventh edition, 1891, p. 104.

<sup>2</sup> Trans. of the Amer. Otolog. Soc. 1875.

<sup>3</sup> Arch. f. Anat. u. Physiol. 1889, v and vi.

the cause of untold misery for the sensitive woman. In the course of time she was operated upon six times with the knife, and caustics of every description and in untold quantities had again and again been used. Electrolysis and hypodermic medication had been tried in vain. The pain produced by these different therapeutic agencies, especially the caustics, and the frequently unbearable pain within the growth had undermined her health. When I saw her, a little over one year ago, there was a solid sessile tumor, the size of about a silver quarter, extending from the region below the tragus into the cheek. The lobule and lower posterior half of the auricle were gone, and from the edge of the rest of the auricle a dense and unyielding cicatricial tissue extended into the integument below and behind the ear. The tumor was flat, about one-sixteenth of an inch elevated above the surrounding skin, ordinarily pale, and not sensitive to the touch. At the time of menstruation it was usually congested, and slightly more elevated, and caused, especially at such times, but occasionally also during the intervening period, the most intense and lancinating pain. The tumor was removed by an elliptical incision in healthy tissues, care being taken to lift it with a portion of the subcutaneous adipose tissue from its location. After severing, by deep incisions, some of the cicatricial bands behind and below the tumor, I was enabled to close the wound by sutures. Primary union. There remained a thin linear scar, the pain disappeared within a few weeks, and there have been no signs of recurrence as yet, fourteen months after the operation. On former occasions the tumor showed signs of reappearance within six months. The microscopic examination made by Prof. Kramer, of the Cincinnati College of Medicine and Surgery, showed the removed tumor to be a true keloid. The epidermis was atrophied, and hairs, hair follicles, and glands were entirely absent. The Malpighian layer was distinctly preserved, but there were only scanty traces of papillæ. Immediately below them, and arranged in layers parallel to the surface, there was a dense mass of fibrous tissue, in which here and there blood vessels, some compressed, appeared. Among the bundles of fibrous tissue occasionally elastic fibers were noticed, and also frequently groups of spindle cells. Below this was a looser connective tissue, with many cellular elements, and a gradual merging into adipose tissue. Of course it is too early as yet to say whether the last removal will be followed by a recurrence. It is true that most authors insist upon the possibility, and even probability, of a return of these growths after operation. But no treatment has as yet been devised that will actually give better results; while Erichsen,<sup>1</sup> though admitting their liability to return after excision, calls this their only treatment. And in this case, the almost intolerable sufferings of the patient, whose best years had been sacrificed in the battle with this baneful disfiguration, compelled me to do something that gave her at least a slight chance of a permanent cure.

These cases do not demonstrate anything new, but having occurred under my own observation lead me to believe that they are still more frequent than we usually think; and while in most cases no serious consequences result from the folly of piercing the ear lobes, yet there occur from time to time cases where a life is at stake or where the enjoyment of life is seriously interfered with. It is time that this relic of barbarism ought to be relegated where it belongs, to the bygone follies of superstition and fashion. And the day is, I hope, not far distant when it will be considered an evidence of brutality to have a tender and unprotected child subjected to such an unnecessary and mutilating procedure.

---

#### DISCUSSION.

Dr. C. R. HOLMES. I have seen three cases in colored women, which, however, were not operated upon. A fourth case, occurring in a white woman 20 years of age, was operated upon four years ago. The tumor occurred on the left side and was about the size of a large hazelnut. It was removed by a V-shaped incision, healing by first intention. There is no recurrence up to date.

Prof. A. POLITZER. I desire to ask Dr. Thorner how many cases of tumor of the auricle, all told, have been seen by him; whether they were all produced by ear-rings, and whether there were any colored people among his patients?

---

<sup>1</sup> The Science and Art of Surgery, Vol. II, p. 314.

Dr. THORNER. The total number of cases of tumors of the auricle seen by me is four. But only in the three reported by me the history of the patients left no doubt that the piercing of the lobe was responsible for the affection. The fourth patient was seen but once and, refusing any operation, was lost from observation. Although these tumors seem to be much more common among the colored race it was strange that all the patients referred to were white.

---

ON A PECULIAR AFFECTION OF THE LABYRINTHINE CAPSULE AS  
A FREQUENT CAUSE OF DEAFNESS.

By Prof. ADAM POLITZER, M. D., University of Vienna.

The subject of the writer's paper is a peculiar form of deafness, occurring usually in the aged and due to a pathological alteration of the labyrinth capsule. During the examination of a number of temporal bones of people who had suffered from progressive deafness, the author remarked circumscribed bony protuberances in the neighborhood of the niche of the fenestra ovalis. These protuberances were of the size of a lentil, rather flattened toward the edges, and contrasted with the surrounding parts by their yellowish color. The mucous membrane of the tympanic cavity was generally normal, occasionally somewhat thickened. The fenestra ovalis was, in some specimens, of normal appearance, in others narrowed by protuberances. The stapes was usually immovable; yet, in very few specimens, slightly movable.

In the second edition of the author's text-book on Diseases of the Ear, published in 1887, may be found a drawing of a case of bony ankylosis of the stapes. Besides changes in the stapedio-vestibular articulation, the capsule of the labyrinth shows considerable enlargement of the lacunar medullary spaces. These changes were interpreted by the author, as well as by others who had observed similar conditions, as being due to chronic interstitial middle-ear catarrh. The study of the specimens which the author demonstrated to the section showed that this view is not correct, and that these cases which have usually been grouped under dry, sclerotic middle-ear catarrh, are in reality due to a primary lesion in the capsule of the labyrinth.

The following are the histological changes observed in the microscopical sections made from the specimens: The parts surrounding the oval window are transformed into a uniform mass of newly formed osseous tissue. The normal articulations between the stapes and oval window have entirely disappeared. The plate of the stapes is frequently thickened, even to five or six times the normal size. The ossificatory changes begin in the bony labyrinth capsule and extend toward the oval window and the plate of the stapes, sometimes even toward the cochlea and the vestibulum. Sometimes the ossificatory changes only produce partial ossification of the stapedio-vestibular articulation, so that in the same section we find one portion of the articulation completely ossified and another still membranous. This partial ankylosis explains why the hearing power for a loud voice is still retained in some cases. The newly formed osseous tissue stains more deeply with carmine, and this difference in color enables us to distinguish the pathological tissue from the normal, even with the naked eye. The number of bone corpuscles is usually increased, the lacunar and medullary spaces are generally larger and contain fibrillar tissue, cells, blood-vessels, osteoblasts, and osteoclasts. It may be well to assume that the changes are due to a primary inflammatory process in the labyrinth capsule, producing a formation of new and young osseous tissue, which successively replaces the normal bone, and by extension toward the stapes and other contiguous parts finally causes the important functional changes due to ankylosis of the stapes. These conditions represent one form of progressive deaf-

ness. That other pathological conditions, entirely different in character, caused by chronic middle-ear catarrh, such as calcifications and ossifications of the stapedio-vestibular ligament, or adhesions between the branches of the stapes and the lower wall of the niche of the oval window may, and do often, produce similar clinical symptoms is a well-established fact. Very little could be ascertained regarding the etiology of this form of progressive deafness, as the disease was observed in old people from whom it was impossible to obtain an accurate history. In two cases gout may be assumed as a possible cause. That syphilis undoubtedly may cause such conditions may be assumed from the investigations made by Moos, who found hyperostotic changes on the labyrinthine wall of the tympanic cavity.

[Specimens and drawings were exhibited and explained by the author, illustrating the conditions described.]

In conclusion the writer refers also to the practical bearing of his investigations; inasmuch as these conditions demonstrate to us why our therapeutic efforts are not always crowned with success. An operation can only afford possibilities of success provided the affection in question has not yet caused ankylosis; and that, even should an operation in some cases bring immediate relief, a permanent result can hardly be expected if the anatomical changes which were exhibited in the specimens are only considered, inasmuch as the affection is progressive, and even the extraction of the stapes would not prevent an obliteration of the oval window.

#### ON THE APPLICATION OF STACKE'S METHOD IN CHRONIC AURAL CATARRH.

By FELIX COHN, M. D., of New York.

The results obtained by the method usually employed in the excision of the ossicles have not been very encouraging, so that the author attempted the application of Stacke's method of operation, which he calls "extra-auricular," in contradistinction to the ordinary method, the "intra-auricular," in these cases. Although no cases of its application in chronic aural catarrh have been as yet reported, *a priori*, this method appeared to have considerable advantages over the usual method, chiefly in that the regeneration of the drum membrane might be prevented if the entire tympanum and the limbus be removed; that the external wall of the attic being removed, a larger area for the impact of sound waves on the stapes and the oval window is provided; that the intra-auricular method does not permit of thorough asepsis; and that, finally, the field of operation being larger the successful removal of the ossicles is in all cases certain. As the operation was experimental in both cases only one ear was operated upon. Two cases are reported.

*Case 1.*—Man, aged 21, operated November 21, 1892, on left ear; suffered from severe tinnitus aurium and progressive deafness. On left ear conversation in low voice not at all audible; loud whisper, 1 inch. Six weeks after operation tinnitus entirely disappeared in operated ear; ordinary conversation, 3 feet; loud voice, 8 feet.

*Case 2.*—Girl, aged 16, suffering from sclerosis and of the ankylosis stapes; operated December 15, on left ear. On examination, hears loud voice at 1 foot; immediately after operation hears ordinary conversation at 1½ feet; loud voice, 8 feet. Six weeks later, hearing is reduced to condition before operation.

The author does not claim any wide applicability of this operation, or the extra-auricular method, in the present state of our knowledge of chronic aural catarrh. Though the success of the experiment has not been brilliant, it has, however, demonstrated the perfect safety of this method, and its availability in cases in which the intra-auricular method is not practicable. With improvement in diagnosis and careful selection of cases, the author believes that better results will be obtainable by Stacke's method than by the intra-auricular method.

## OPENING THE MASTOID CELLS IN ACUTE INFLAMMATORY MIDDLE-EAR DISEASES.

By L. D. BROSE, M. D., PH. D.,

*Oculist and Aurist, St. Mary's Hospital, Evansville, Ind.*

Although the indications as laid down in the text-books for opening the mastoid cells in acute inflammatory middle-ear diseases seem well defined, it has nevertheless been my experience to have met with cases where mastoid swelling and edema were present associated with pain and fever and other symptoms, usually indicative of mastoid cellular involvement, where, owing to failure to obtain consent of the patient to an operation or through other causes, delay was encountered, the patients eventually made a perfect recovery under simply local treatment. Dr. Knapp, of New York, seems to have had a similar experience, for in a recent report<sup>1</sup> of a so-called case of "Bezold mastoiditis with operations," he states that he is afraid at the present day there is too great a tendency to opening the mastoid and the skull, and that precision in the determination when to or when not to operate can only be obtained by a critical comparison of many fatal cases. As an exploratory operation, he thinks mastotomy not yet harmless enough to be justifiable in many cases. To more minutely bring up the symptomatology of the subject and describe a method of operation, I will relate several of the cases which, in my opinion, justified opening the mastoid cells.

Mr. J. E., 41 years old, came to me early in July, 1891, with right-sided otorrhœa, accompanied by pain in the temple and frontal region. The disease was of ten days duration, and previous to this time he had never had ear trouble. By gentle syringing with warm water the external auditory canal was freed from pus, showing slight edema and swelling of its walls and middle-ear pulsation. Pressure over the tragus and mastoid region elicited soreness, but little or no pain. Treatment, three Swedish leeches in front of the ear, hot-water instillations of fifteen minutes duration, frequently repeated, and later insufflations of dry powdered boric acid. July 26, otorrhœa cured and patient passed from under observation, complaining still of nocturnal pain. In the following October he had an attack of meningitis, for which he was treated by Dr. A. M. Owen, and finally resumed his business, that of shoe merchant, in December. During the meningeal attack the ear pains returned in severity, but unaccompanied with otorrhœa. Patient continued to complain of earache off and on, and finally again consulted me in March, 1892. At this time there was neither swelling nor tenderness in front of or back of the ear. The drum perforation in the lower and posterior quadrant was almost wholly closed, with the hearing of ordinary conversation fairly good. April 14, consent was obtained, and after shaving the scalp around the ear region and carefully washing the side of the head with a 5 per cent solution of carbolic acid, an incision was carried down to the bone just upon a line with the ear insertion some 2 inches in length. Strong retractors were inserted and the wound widely separated. The bleeding, which was light, yielded to compression. With hammer and chisels a funnel-shaped opening was made into the temporal bone upon a line with the upper border of the external hearing canal and parallel to its axis down to the mastoid cells, and a small quantity of pus liberated. The operation, which had not required more than ten minutes, was terminated by packing iodoform gauze into the wound and placing over this a pad of absorbent cotton moistened in sublimate water and a retaining bandage. After the third day the dressings were renewed almost daily until the patient's complete recovery and discharge, May 24, 1892.

Mr. A. De F., 71 years old and a practicing physician, came to see me about April 20, 1892, for profuse left-sided otorrhœa, attended with violent pains all over the side of the head. His history was that he went outdoors the last Sunday in March, 1892, a cold, raw day, without a hat or head covering, from which he took severe cold in the head, followed during the night with earache. For several years previous to this he had been hard of hearing in the right ear through dry chronic middle-ear catarrh, which in turn followed chronic naso-pharyngeal catarrh, with which for years he has been afflicted. The present otorrhœa set in five days after

<sup>1</sup> Archives Otology, July 9, 1892.

the earache, mitigating but little this terrible pain, for the relief of which he has been daily resorting to powerful narcotics. The region in front of the tragus was swollen and tender and the patient was much annoyed by a "slushing" in the external auditory canal when he moved the jaws in speaking or eating. The discharge from the ear was ropy, very copious, without odor, and the canal lumen so encroached upon by its swollen walls that little could be seen of the drumhead. The mastoid region was not swollen, but tender upon firm pressure. Treatment, hot-water instillations, followed by a 10 per cent solution of cocaine when there was severe pain and large doses of chloral hydrate at bedtime. No improvement resulting, three Swedish leeches were applied over the tragus, followed by Leiter cold-water ear coil. During the flow of very cold water the pain would almost cease, only to gradually return with increased severity after its discontinuance. The patient, because of his age, was loath to take an anæsthetic and have the mastoid cells opened. Finally, June 2, he consented, and after the usual antiseptic preparation of the field of operation, a long incision along the line of ear insertion was made, the mastoid cavity opened with chisels, considerable pus evacuated, and a communication reestablished with the middle ear and through the Eustachian tube with the pharynx. After each irrigation with a weak solution of sublimate water, fluid invariably entered the throat. The pain became less, narcotics which had been used for two and one-half months were dispensed with, and recovery slowly followed. July 6, 1892, he returned to his home, the perforation in the drum membrane healed and hearing restored to ordinary conversation.

Amos W., 28 years old and a farmer, came November 5, 1892, with a history of having used cold salt water as a snuff in the September previous for the cure of chronic catarrh. In a few days left-sided earache resulted, followed by an ear discharge of bloody serum, which later became purulent. He was treated in a neighboring village and cured by boric-acid insufflations of the otorrhœa, but thereupon followed an edematous swelling back of the ear, with at times return of the ear pain. An ointment of mercury and belladonna was prescribed, with frequent poulticing. During the next two months the swelling back of the ear would decrease and again increase, with at times slight otorrhœa. December 6, 1892, mastotomy was performed in the manner described in the preceding cases, and a small quantity of pus found in the mastoid cells. Result, recovery in seven weeks, with hearing improved to watch at 2 feet.

In reviewing the indications which lead one to determine whether a mastotomy should or should not be performed in a case of acute middle-ear disease, I can not too strongly advise against permitting the presence or absence of any one symptom to determine the point in every and each instance, but rather to make a study of each individual case in all of its symptomatology, with proper consideration of the result of recognized good previous treatment. Schwartze says,<sup>1</sup> at the furthest, after eight days of antiphlogistic treatment, especially ice applications, if the pain, edema, and fever have not ameliorated, the operation is indicated. Further along, though he qualifies this positive assertion somewhat, and says that while in most cases unbearable and uncontrollable pain in the mastoid region, radiating from thence into the head region around, urge one to operation, they are, nevertheless, and to a high degree, uncertain in determining suppuration in the mastoid. Redness, edematous swelling, and marked tenderness over the bone on pressure may be due to localized periostitis, not in anyway connected with middle-ear inflammation. The most reliable symptom of acute suppurative mastoiditis, in his opinion, is stenosis of the external auditory canal through swelling and bulging of the posterior and upper wall, with edematous skin inflammation just below the apex of the mastoid process. Deep-seated furunculosis of the external auditory canal, however, must be excluded.

In the course of acute purulent otitis media without involvement of the mastoid and without retention of secretion, Dr. Heimann, of Warsaw,<sup>2</sup> thinks mastotomy indicated if the otorrhœa remains profuse and does not yield after a certain time (two or three weeks) to the usual methods of treatment. Where ear drainage, after perforation of the drum membrane through swelling of the mucous lining of the middle ear or great stenosis of the external auditory canal, is insufficient,

<sup>1</sup> Second volume Handbuch der Ohrenheilkunde, 1893.

<sup>2</sup> Archives Otology, Vol. xx, No. 2.

the operation may be indicated as a prophylactic measure, in the prevention of death through imperfect disinfection. Cerebral abscess, brought about by acute, suppurative, middle-ear disease necessitates opening of the mastoid, for without it the termination is invariably rupture into the ventricles, or fatal meningitis. We suspect this condition through pressure symptoms on some of the cranial nerves, speech disturbances, or by ophthalmoscopic eye examination disclosing changes in the eye ground and vessels, with or without irregular fever, chills, delirium, stupor, drowsiness, and coma. Suppurative phlebitis with thrombosis of the lateral sinus as well as extradural suppuration are in many cases not distinguishable from deeper-seated abscesses and call for operative treatment as well, even if septic or pyæmic symptoms have occurred. When the thrombosed jugular vein can be felt as a hard, painful cord along the sterno-cleido-mastoid muscle, we have all the more reason to suspect involvement of the sinus, but it should not be forgotten that the vein accompanying the lymphatic plexus may, through inflammation, likewise occasion this tenderness when the sinus and internal jugular are perfectly healthy. Persistent headache, nausea, vomiting, and dizziness, with diminished, otorrhœa, may signify meningitis. Still the boundary between meningeal irritation superinduced by the middle-ear inflammation and meningitis proper is not at all sharply defined and calls for the exercise at times of unusually clear judgment. Repeated and obstinate attacks of mastoid neuralgic pains, unassociated with fever, or even loss of hearing, and which resist antineuralgic treatment, can at times be alone cured by mastoid resection.

The region for a mastotomy operation may be defined as just under the linea temporalis, above and just back of the posterior wall of the external auditory canal in front; a layer of bone from one-sixteenth to one-eighth of an inch thick usually separating the mastoid antrum and the inner end of the bony external auditory canal. Following Hartmann, of Berlin, my first incision is from  $1\frac{1}{2}$  to 2 inches long and just back of the insertion of the ear muscle, with the center corresponding to the upper edge of the external auditory canal. After thoroughly scraping away the periosteum a funnel-shaped canal is carefully chiseled out of the temporal bone, layer by layer, in a direction inward and forward and parallel to the axis of the auditory canal. Frequent examination with head mirror, ear speculum, and, when in doubt, the ear sound in addition, keep me informed as to the depth of penetration as well as its course. When pus is reached, and there has been no reason for suspecting extensive bone involvement, the operation is terminated with the removal of just enough bone to give good drainage. For more extensive suppuration and where the attic is largely the seat of the disease the posterior wall of the inner end of the auditory canal may likewise be removed and a drainage tube at times carried through the new-formed opening and out of the external meatus. Iodoform gauze keeps the wound open and serves as a dressing next to the bone, and over this a layer of absorbent cotton and a bandage is placed. Good results, however, can be obtained in many cases equally well with drill, chisel, or trephine, more depending upon the operator and his anatomical acquaintance with the neighboring blood vessels, nerves, and cranial contents, with careful and well-regulated after treatment, than upon the instruments with which the operation is performed.

---

## CHRONIC DISEASE OF THE MIDDLE EAR; ITS PROGNOSIS AND SURGICAL TREATMENT.

By ALBERT H. TUTTLE, S. B., M. D., of Cambridge, Mass.

The treatment of the chronic dry form of aural catarrh has always been an unsolved problem with the profession, and even to-day adequate means for its prevention or cure are unknown. It was with the hope of relieving the deafness

resulting from this disease, sclerosis of the tympanum, that Schwartz, for the first time, removed the membrana tympani and malleus in 1873, and by his precdence encouraged others to undertake similar operations. Soon after Schwartz, Kessel took up the subject, and did much to establish the operation. He removed all the ossicles and insisted that good results in hearing could only be expected when the stapes was removed. In 1880 Weber-Liel reported a case of dizziness, following a destruction of the stapes, with loss of labyrinthine fluid. Bishop operated 14 times by simply removing a small piece from the membrana tympani in 1885. In 1886 Rossi in 2 cases disarticulated the stapes from the incus, and Sexton introduced the operation of removal of the larger ossicles and membrana tympani in certain cases of persistent suppuration of the middle ear. In 1887 Baracz removed the membrana tympani and larger ossicles for tinnitus aurium, and the following year Burnett performed the operation for a similar purpose. In 1888 Berthold while operating on the middle ear accidentally removed the stapes complete and observed as the result a great improvement in hearing. The cases which were operated upon by removing membrana tympani and ossicles now began to increase rapidly in number; Stacke reported 10 cases and Sexton 29, treated for chronic suppuration of the middle ear in this manner, and soon after 28 cases were reported by Wetzell, 32 by Ludwig, and 20 by Colles; Schwartz, in two and one-half years, operated on 151 cases; Milligan reported the results of 4 operations. During these later years the operation became limited almost exclusively to cases of chronic suppuration, and it was not until the last (1892) that the operation, in modified form, was revived for its earlier indication, the relief of chronic deafness by Jack, who operated for the simple removal of the stapes. Since then the latter operation has been performed by Blake, Burnett, and others. As to the result of these manifold operations, deafness has been greatly relieved in many cases, in others slightly, whereas some have received no improvement or even have been made worse; most of the cases of chronic suppuration have been cured or greatly relieved; tinnitus aurium and vertigo have been relieved, as a rule, but the accompanying deafness usually has remained unchanged.

From this mass of material several facts can be established, viz, that in certain cases of chronic deafness great improvement in hearing follows the removal of the ossicles, in part or whole, with and without the membrana tympani; that, in certain cases of chronic deafness of apparently middle-ear origin, the complete removal of the stapes is unattended with improvement in hearing; that the removal of one or all the ossicles and membrana tympani is not productive by itself of any great degree of deafness;<sup>1</sup> that incisions in the membrana tympani heal rapidly by first intention, when the ear is properly prepared and prior to the operation is free from suppurating processes; that the operation is attended with but slight inconvenience to the patient, the total disability lasting, as a rule, not over twenty-four hours, and with no risk of life of itself; that the treatment of chronic suppurative otitis media by removal of the remains of the membrana tympani and ossicles for the purpose of eliminating causes, such as carious bone, and establishing free drainage for the discharge of pus is a legitimate and purely surgical practice, which is just as applicable here and is followed by as good results as in most other parts of the body; and, finally, that certain cases of tinnitus aurium and vertigo are benefited by releasing the stapes from its attachment to the incus and surrounding adhesions.

With these facts before us it is obvious that in certain cases of chronic deafness there are surgical measures for relief, but the difficulty at present lies in the

---

<sup>1</sup> Würdemann has reported a single instance where total deafness followed the removal of the ossiculæ for chronic aural catarrh, which he thought was due to hæmorrhage into the labyrinth, with the formation of a clot and its subsequent organization.

inability to recognize, among those who will not, the cases which will yield good results from operation. As it is yet impossible in many cases to distinguish deafness due to middle ear causes from that of central origin, changes in the nerve or internal ear, and as the results of operative treatment in the latter classes must necessarily be of a negative character, it is very important in consideration of the prognosis to study intimately the minute differences in the symptoms of cases which yield unlike results and especially after the successful removal of the stapes, since by this means the contra-indications of the operation can be more clearly determined.

The number of cases which the writer has had the opportunity of studying is too small for the basis of a just conclusion, and recourse has been made to a study of the reports of similar cases in the practice of others; however, one thing is very obvious, and it requires very little experience to prove it, i. e., the great difference in the bond of union between the foot plate of the stapes and the margin of the oval window. Furthermore, when the stapes is removed with great difficulty, perhaps only after the foot plate has been broken, and in small pieces, the improvement in hearing is usually great and, on the contrary, when it is easily removed, often by simply pulling on the head with a hook inserted between the cruræ, the hearing is usually unchanged by the operation.

It would seem, then, that deafness is an indication for operation only in those cases where the stapes is firmly fixed in the oval window, and the firm fixation of the stapes is found especially in chronic dry catarrh of the middle ear, sclerosis of the tympanum, the principal symptom of which is deafness, of insidious origin, continuous and progressive in character, and the chief pathological changes, that are recognized late in the disease, are a thinness of the membrana tympani, which is usually of increased transparency, often retracted and immobile; a rigidity of the chain of ossicles; an atrophy of the cruræ of the stapes, and firm fixation of the foot plate, often by osseous union with the margin of the oval window. In making a diagnosis of this trouble the chief considerations to be borne in mind are the history of the insidious onset without suppurative changes and the freedom of the membrana tympani from old scars or adhesions. Complicated cases can not always be recognized with certainty. In cases of tinnitus aurium, Menière's disease, deafness following acute and chronic suppurative otitis media, also deafness due to senility and calcareous deposits in the membrana tympani, the stapes is easily removed, but in these cases there will be no great improvement in hearing as a result of its removal; therefore, the operations should not be undertaken for the relief of deafness. The condition of the hearing after the removal of the stapes is better in recent cases of dry catarrh, where it may become nearly normal, than in the older cases; this seems to indicate that as a result of the long-continued fixation of the stapes certain changes occur in the deeper structures of the ear and gives rise to the question of early operation for the prevention and arrest of the progressive deafness in cases of established dry catarrh, where the diagnosis is certain, but as yet the hearing is not greatly impaired.

The writer does not wish to convey the impression that this is the only class of cases where a removal of the ossicles will be followed by an improvement in hearing, but that with our present knowledge it is the only class where the diagnosis is fairly certain and the patient can be assured of a reasonable improvement in hearing from a successful operation. When ankylosis of the ossicles from any cause is broken up the hearing will be improved if there exists no deeper causes of deafness, but here the exact state of affairs can only be determined by the operation, and therefore the result is uncertain. If the stapes is firmly fastened in the oval window by bony deposits, little improvement in hearing can be expected from its disarticulation with the incus, a practice that has been followed by some few operators. In giving a prognosis of an operation for the removal of the stapes

an important fact to be borne in mind is the great difficulty of extracting the foot plate in those cases where there is ossific union with the margin of the oval window: where the external meatus is very narrow or the window is concealed from view it may be impossible to extract the ossicle.

In chronic suppuration of the tympanum the continued formation of pus depends chiefly upon the retention of the inflammatory products from want of a proper outlet, granulation tissue, caries of the ossiculæ, or walls of the middle ear, cholesteatomata of the attic, aditus, or antrum, and chronic mastoid inflammation, and it is very difficult to determine which of these causes are active in producing the discharge of a given case. Under these circumstances the treatment of chronic aural suppuration should be governed by a proper spirit of conservatism, and, except in certain cases, the older and milder means, such as douches, with the occasional cleansing of the tympanum as well as possible by the physician, removal or cauterization of granulations, and application of mild anti-septic solutions or powders, should be persisted in until it becomes obvious that no result will come from these measures.

Those cases where in the beginning the diagnosis of mastoid disease is clear form an exception to the above, and as spontaneous cure is rare and considerable danger of cerebral complications exists so long as the suppuration continues, an early operation is advisable. Cases are sometimes presented where the suppuration has persisted for years, and under these circumstances it is reasonably assured that there are causes present which require immediate surgical treatment. Many of these cases have only a very small outlet for the discharge, situated in the upper posterior segment of the membrana tympani, and surrounded by thickened edges which increase in size with every acute exacerbation, make smaller the narrow channel and threaten its complete occlusion. The latter class can be recognized at sight by the pathological appearances of the membrana tympani in consideration with the history of continued suppuration, and demands early operative treatment. It is the writer's opinion that an ear which has healed without operation, with the formation of dense scar tissue, and strong adhesions between the remains of the membrana tympani and inner walls of the tympanum, so as to close off completely the cavity of the middle ear from external and atmospheric influences, is less liable to recurrent attacks of suppuration than those where the ossicles and membrana tympani have been removed. Vertigo and tinnitus aurium when caused by adhesions between the membrana tympani or ossicles and the inner wall of the tympanum indicate the necessity of surgical interference, but when the cause of these symptoms are not manifest on examination of the parts treatment of any kind is experimental.

There remain for consideration two classes, which Kessel has tabulated among the conditions requiring a removal of the membrana tympani and ossicles, viz, entire calcification of the membrana tympani combined with difficult hearing and a normal acoustic nerve, and cases of incurable occlusion of the Eustachian tube. In the former class it is impossible to determine that the acoustic nerve is in a normal condition, and with a rigid membrana tympani there may exist, without recognition, ankylosis of the ossicles, or even firm fixation of the stapes. The writer found a considerable absorption of the remains took place after the removal by excision of one-half of a large horseshoe-shaped calcareous deposit, beginning at the line of division and developed by the hyperæmia and other changes incident to the process of repair. Therefore it seems to him that, if the exact conditions set down by Kessel could be determined, milder measures than the removal of the membrana tympani and ossicles, such as simple incision or the removal of pieces of the deposit, might be practiced with equally as good results in these cases. The cases of incurable occlusion of the Eustachian tube are very rare, and none have come under the writer's experience; however, he would suggest as a prelimi-

nary operation the production of a triangular-shaped opening in the membrana tympani with the base downward, made from an inverted V-shaped flap, which have been shown by v. Troeltsch and McKeown to remain patent for a long time.

From the above it will be seen that the principles governing the operative treatment of these middle ear affections are of two different types, and the cases have been divided into two groups accordingly, by Stacke, viz: The first, cases of chronic suppuration, often imperatively demands surgical interference to save life, whereas the second class, cases of deafness, tinnitus aurium, etc., resorts to surgical treatment merely from the hope of improving hearing, relieving the distressing tinnitus, or other conditions of no vital importance. In the first group, immediately after the operation severe and even alarming symptoms sometimes appear and depend largely on the condition of the diseased ear, the skill of the operator, the extent to which the parts are removed, and the accidents peculiar to the seat and circumstances of the operation. Nausea and dizziness are the particular symptoms after the surgical treatment of the second group, and the patient experiences but little discomfort from the operation.

The extent to which the parts have been removed and the method of operating has been varied considerably by different men, and therefore it is important to define the exact limits of the operation necessary in a given case to give the best results with the least inconvenience to the patient. In cases of chronic suppuration most operators have found that an improvement in hearing follows the removal of the membrana tympani and larger ossicles, and that this improvement is partially lost when the membrana tympani re-forms. It is on this account that many operators remove the membrana tympani as completely as possible and prevent its re-formation by such means as the application of caustics or secondary excision. In the same class of cases there is also under debate the question, what ossicles shall be removed, and here the argument is concentrated especially upon the extraction of the incus. Furthermore, when the disease has extended to the antrum, the simple excision of the membrana tympani and extraction of the larger ossicles sometimes will not be sufficient to effect a cure, and therefore Stacke devised his method for operating in these cases, by which the bony partition between the malleo-incudal space, the aditus, and antrum and the external meatus is removed and a free communication established between these cavities.

In the writer's opinion, deafness is of secondary importance in suppurating cases, and a re-formation of the membrana tympani, which will shut off the deeper cavities of the temporal bone, is of greater value to the patient than the slight improvement in hearing that attends its non-development. Therefore in the treatment of this affection it is advised to remove as little as possible of the membrana tympani, that its re-formation will be better assured; the malleus should be withdrawn after cutting close around it to free it from adhesions with the membrana tympani, taking especial care to free the articular head, and the incus should also be extracted when it can be easily without injuring the neighboring parts. The removal of the incus brings with it, as a rule, any remnants of the head of the malleus that may have been left after the latter ossicle has been extracted in the carious condition and makes a free communication between the lower portion of the tympanum and the attic, aditus, and antrum. The ossicle is sometimes the seat of carious changes.

The removal of the incus is therefore desirable, since it enables the operator to better cleanse the middle ear, prevents the ossicle from becoming a foreign body, eliminates a possible source of continued suppuration, and liberates the head of the stapes from part of its attachments. With deep-seated inflammation in the mastoid, the radical operation proposed by Stacke or some of the various mastoid operations will often be necessary to effect a cure.

In the earlier operations for the relief of deafness the removal of all the ossicles was recommended, but later the observations of Jack and Berthold showed conclusively that in cases where the stapes is removed the hearing is better after the opening in the membrana tympani is closed, and that the removal of the stapes is the essential part of the operation. In removing the stapes, the incus is frequently loosened and can be easily extracted without increasing the reaction or time required for healing. If dislodged during the operations on the tympanum it is liable to become a foreign body unless removed.

*Case 1.*—Martin F., aged 23 years, has had chronic otorrhœa of left ear for twelve years. The membrana tympani and malleus were removed February 8, 1891, and the tympanum treated carefully with antiseptic solutions, but the membrana tympani quickly re-formed, and it became necessary to repeat the operation. The second excision of the membrana tympani was performed by Stacke's method, and at the same time some carious spots on the posterior wall of the tympanum were curetted. The latter operation was performed December 9, 1891, was more thorough than the preceding, was not followed by a re-formation of the membrana tympani, and resulted in an almost cessation of the discharge. At the end of three months only a slight amount of moisture could be found in the tympanum after the patient had been lying down for some hours (a symptom of suppuration of the antrum). A great improvement in hearing accompanied the reparative changes of the middle ear.

*Case 2.*—William D., aged 35 years, has had dry catarrh of the tympanum with marked deafness for more than five years. The membrana tympani, malleus, and incus were easily removed September 11, 1892, and resulted in an improvement in hearing. The membrana tympani re-formed in a short time and the improvement in hearing was partially lost.

*Case 3.*—Mr. F., aged 55 years, has had dry catarrh of the middle ear for twenty years, and at present deafness is very marked. October 24, 1892, the incus was removed, but in attempting to extract the stapes both cruræ broke off short, leaving the foot plate in the oval window. The incision in the membrana tympani healed rapidly, but the improvement in hearing was very little and not at all satisfactory.

*Case 4.*—Lydia P., aged 33 years, has had a chronic otorrhœa for ten years, and when examined there was a mass of polypi in the meatus, excessively sensitive to the touch; a large perforation in the membrana tympani; an entire absence of the malleus and a large opening in the posterior upper wall of the meatus, which extended through the bony wall, formed a free communication with the antrum, and showed the existence of mastoid disease, with an attempt on the part of nature to form a spontaneous cure. The patient was treated in a conservative manner for two months, but showed no improvement, and it was decided to operate October 26, 1892. The remains of the membrana tympani, a mass of inflammatory tissue, some carious bone, and several pieces of a cholesteatomatous growth were removed, and the opening between the antrum, tympanum, and meatus enlarged. The patient reacted badly, and there were symptoms of severe meningeal irritation; however, by careful and repeated cleansing and keeping the drainage free, these symptoms abated at the end of ten days, during which time large masses of cholesteatoma were discharged from the meatus. The suppuration entirely ceased at the end of the sixth week, a clean scar formed over the diseased places, and a considerable improvement in hearing followed.

*Case 5.*—Mary C., aged 21 years, has had chronic otorrhœa of both ears for several years. After treating the parts in the usual way for several months, the membrana tympani and remains of the malleus and incus were removed from the ear which was most diseased November 6, 1893. The incus was found to be normal but the malleus, which was removed intact, had almost completely ulcerated away, leaving but a small portion of the head about the joint. Suppuration entirely ceased at the end of eighteen days, the membrana tympani did not re-form, and the hearing was considerably improved. By continued treatment the discharge of the opposite ear was stopped, but a large perforation remained in the membrane. The hearing is about the same in both ears. During the past six months there have been recurrent attacks of suppuration in both ears.

*Case 6.*—John B., aged 57 years, has been afflicted with non-suppurating disease of the middle ear for ten years, and Menière's disease for five years. The membrana tympani and all the ossicles were removed in December, 1892, and as a result there were severe dizziness, vomiting, and nausea, for nearly a week, the noises in the head ceased for twenty-four hours, and then they returned with

increased force. The vertigo returned in paroxysms and was as bad as before the operation. The hearing was unchanged. The operation revealed a small exostosis on the inner wall of the tympanum near the round window.

*Case 7.*—John K., aged 30 years, has had chronic suppuration of the left ear for three years. When first seen the patient was suffering from an abscess which pointed in the mouth, on the left side, near the hamular process, and probably found origin in the middle ear disease, from which it descended along the tissues forming the Eustachian tube. The membrana tympani was greatly thickened and contained a large perforation. The abscess healed rapidly after it was freely incised, but persistent treatment failed to stop the suppuration, and at the end of three months, January 8, 1893, the remains of the membrana tympani and malleus were removed. Facial paralysis and free suppuration followed the operation and continued for two months, when the discharge ceased and a recovery from the paralysis soon occurred. The membrana tympani did not re-form and a considerable improvement in hearing took place.

*Case 8.*—Samuel J., aged 53 years, has had progressively increasing deafness for twenty-five years, due to dry aural catarrh. The stapes was removed in pieces with great difficulty after both cruræ had broken off, and a great improvement in hearing is the result. Operation January 8, 1893.

*Case 9.*—George C., aged 60 years, has had marked deafness, the result of chronic suppurating otitis media, for which the stapes was removed in its totality February 12, 1893. The operation was easy, although the membrana tympani was closely bound to the promontory with old adhesions. The result was entirely negative.

*Case 10.*—Sarah C., aged 24 years, has had marked deafness due to dry aural catarrh, for which the stapes was removed in pieces March 14, 1893, with great difficulty. The improvement in hearing was very great and brought the ear very near its normal ability. The deafness had been very bad for three years only.

*Case 11.*—Mr. B. J. R., age 55 years, has had progressively increasing deafness for twenty years, which was apparently due to a large horseshoe-shaped calcareous deposit that partly surrounded the manubrium and occupied nearly the whole of the membrana tympani. March 18, 1893, one-half of the calcareous plaque was removed with very little improvement in hearing; and later, April 7, under cocaine anæsthesia, the stapes was partially removed and followed by considerable relief of the deafness.

## THE INDICATIONS AND PREFERABLE METHODS FOR MASTOID OPERATIONS.

By SETH SCOTT BISHOP, M. D., of Chicago, Ill.,

*Surgeon to the Illinois Charitable Eye and Ear Infirmary, etc.*

When and how shall we operate in mastoid disease? Among American surgeons there is a wide diversity of opinions, especially as to what symptoms constitute a positive demand for opening the mastoid process. My observations leave the impression that the majority of surgeons are too conservative, both as to the time selected for surgical interference and the extent of the operation. While conservatism is an admirable trait in a surgeon, so long as caution is not merged in timidity, so far as I have seen its influence in this class of cases it has proved detrimental to the patients. I have seen fatal results follow (1) refusal to allow the operation; (2) after operations too long deferred, and (3) after operations that were performed too timidly to remove all the diseased tissue, but I have never known death to occur as a direct result of the operation itself. We all appreciate the gravity of this undertaking, but in view of the fact that the disease demanding it is far more dangerous than the surgical measures for its relief, greater freedom of action and boldness of methods will add luster to the records of our work.

When shall we operate? The weight of experience and the testimony of trustworthy authorities favor early operations. If we wait for the very grave symptoms; fever, rigors, vomiting, vertigo, widely diffused pains in the head and neck, thickly furred, tremulous, and indented tongue, delirium, etc.; the chances of success are discouragingly diminished. I do not believe it is wise to postpone

an operation until these symptoms occur, unless the patient is suffering from some other affection that renders recovery hopeless, or unless the prostration is so great as to preclude the possibility of survival. There are tentative methods of treatment that are proper and promising in incipient mastoiditis unattended by urgent or dangerous symptoms. I have often subdued periostitis by the use of counter irritation, compresses, and the free extraction of blood by leeches and wet warm applications. Many cases of mastoid disease may be cut short by this early active treatment. I have seen very acute attacks with intense pain relieved permanently in this manner. If there is also acute inflammation of the middle ear, additional leeches should be applied about the tragus and an opiate given. If decided relief does not occur within twenty-four or forty-eight hours we should not hesitate to make Wilde's incision, or if this does not relieve, open the bone. This statement, in my opinion, embodies as great conservatism as our duty to the patient justifies. Obviously, any rules that may be laid down are more or less elastic. For example: A case recently came under my observation in which the mastoid had been opened. Another fluctuation swelling appeared above the auricle. I advised opening it, and pus was liberated. Subsequently the patient was brought to me with this opening almost closed, but pus could be pressed from it. There was severe periostitis involving the whole mastoid, temporal, and zygomatic regions. I advised free incision extending through the two previous openings, but one of my assistants, Dr. Holinger, desired to try the effect of pressure with antiseptic compresses. This treatment alone dispelled all the threatening symptoms in less than two days.

I have formulated the following six rules by which I have been guided in deciding the perplexing question of an operation: The mastoid process should be opened (1) when there is acute inflammation of the bone that resists palliative treatment; (2) when repeated swellings and abscesses occur; (3) when there is bulging of the posterior and superior wall of the meatus with middle ear suppuration; (4) when there is a fistula; (5) when there are severe pains in the same side of the head as the diseased ear, resisting all other treatment (mastoid cell inflammation); (6) when a foul otorrhœa can not be cured by any other means. These rules may be said to be conservative, and whatever deviation we may indulge in ought to be at once favorable to the operation and the welfare of the patient. Too great temporizing favors sinus thrombosis, septicæmia, brain abscess, and meningitis.

What method of operating shall we pursue? I have usually performed Schwartz's operation, but have also used Stacke's method with gratifying results. It is one of the most difficult, delicate, and dangerous operations in surgery. Since one can not know the extent of the pathological process before entering the bone, it does not appear to be advisable to decide upon any special method of procedure in advance save one: Remove all dead and diseased tissue. Whoever does this does best. Stacke's and Bergmann's operations have the advantage of affording the greatest accessibility of the tympanum, so that if it is necessary to remove necrosed ossicles or diseased tympanic tissue it can be done with greater facility and thoroughness. But it is best to guard against collapse of the walls of the meatus and resulting stenosis by inserting a tube in the canal. Schwartz's operation is sufficient for most cases. It is much simpler and leaves a less extensive wound. The operations of Wolf and Kuster through the meatus I have never ventured upon for fear of not possessing sufficient skill to remove all the diseased tissue through such a narrow field of vision. All these operations are described in the admirable monograph on the surgery of the ear by Albert H. Tuttle, of Boston.

There are a few points in this connection worth mentioning, for they are closely related to a successful issue. The best illumination is gained by the use of light

reflected from the mirror on the operator's forehead. This affords a decided advantage over direct illumination. The light is more intense, can be thrown into the opening of the bone in every direction, and there are no shadows to obscure the field. It is safer not to close the wound entirely until it has healed from the bottom. When the interior has filled with cicatricial tissue up to the surface of the outer table, it is safe to allow it to close. I have had good results after closing the wound completely at the time of operation, but it is certainly not so safe a plan. The best dressing is aristol sprinkled over the wound surfaces to cover them entirely. Then iodoform gauze should be placed lightly in the mouth of that part of the wound chosen to remain open. It should not be packed down to the bottom of the wound so as to crowd any discharges inward, but it should extend just far enough inward to keep the cutaneous tissues from closing over the superficial opening in the bone until the deep wound is well. Aristol has two excellent qualities: It is the best cicatrizant we possess, and it has the additional advantage of being to some extent an anæsthetic. While iodoform is irritant and toxic, and boracic acid sometimes produces pain, aristol soothes and heals without any ill effects. After stitching that part of the wound to be closed and dressing the open mouth for drainage, the whole is covered with iodoform gauze, absorbent cotton, and a net bandage. This bandage is made of the common mosquito netting, which, as used in the Northern States, is sized with a preparation of glue. The roll of bandage is dipped in water, just before applying, until it is wet through. Then the water is squeezed out and the bandage applied as usual. When it dries the layers adhere together firmly, so as to retain their position for many days in succession without interference.

But the most perplexing question before us is, When shall we open the bone? My conviction is that the earlier the operation is performed the better our records will be. We should operate while the condition of the patient favors resolution instead of dissolution, and all dead and diseased tissue should be removed. The safest and simplest rule by which I have been generally guided is this: When there is a fistula, or a group of unyielding symptoms of serious sickness undoubtedly due to the ear disease, penetrate the bone. Unlock the vault that holds our treasure and the sufferer's doom. Give vent to the pent-up furies of disease, as *Æolus* loosed the struggling winds. A merciless and unrelenting foe has stormed the fortress of the brain; the citadel of life. No truce is safe, and now heroic action only conquers man's great foe.

---

#### DISCUSSION.

Dr. C. R. HOLMES, Cincinnati, Ohio. I can not agree with Dr. Cohn that the operation by Stacke's method is more aseptic than when the operation is performed through the external canal. The results from the operation in chronic catarrh of the middle ear have been anything but satisfactory, and therefore there is little to justify us in making such an extensive operation as proposed. I do not think that drills and trephines, as mentioned in Dr. Brose's paper, should even be considered as a part of the armamentarium of the modern aural surgeon. They are instruments that had their day and defenders, but are, and justly so, relegated to the past. I am not in favor of using the drainage tube, as described by Dr. Brose, passing through the opening in the mastoid into the middle ear and out of the external canal; because, if the disease warranted such an extensive interference with the middle ear, the method of operation is not radical enough; and if only for the purpose of giving vent to the mastoid cells, it is not good surgery to meddle so much with the middle ear and endanger the position of the ossicles. I have examined cases where the stapes had been removed; Schwartz's and Lucae's experience have been very unsatisfactory. I read a letter recently received from

Prof. Schwartz and another from Dr. Stacke, wherein both spoke unfavorably of the operation; and Prof. Schwartz, referring to the reports by Dr. Jack, declared that the time for judgment upon these cases is entirely too short, and at present he does not believe the results will be what has been claimed. I agree with Dr. Bishop that aural surgeons have been too conservative in operating, and it is especially true that many do operate, but are too timid. If we have once determined that it is necessary to operate, we should use the utmost care to guard against opening into dangerous parts, but we should be bold enough to remove all the diseased tissue. I beg to call the attention of gentlemen to the fact that Wilde's incision should not be practiced. Schwartz has omitted it in his last work because it is painful, and, if the disease has advanced far enough to warrant the operation, the cells in nearly every case are also involved, and the patient can only be benefited by opening the bony cortex. If the flap is formed from the lining of the external canal, according to Stacke there can be no collapse after the operation, and with proper packing stenosis should never occur. In the experience of the speaker, the canal will admit of the largest-sized speculum being used, and every part of the cavity can be freely inspected. We do not expect the cavity formed by the removal of diseased tissue to be refilled with cicatricial tissue; in fact this is the most undesirable thing that can happen. What we do want is a cavity covered with healthy epithelial cells; and this can never be accomplished unless firm and persistent packing is practiced until all of the cavity is covered with epithelium.

Prof. N. POLITZER. I never open the antrum in acute cases. The mastoid trouble is, in acute cases, rarely in communication with the antrum, and it is better simply to open the mastoid cells. We have thus a clean wound, which closes rapidly; the suppuration in the middle ear ceases sooner, and hearing returns. Of late I have tamponed the wound for one or two days with iodoform gauze; in fact I have sometimes closed the wound immediately after the operation by sutures, after having, of course, scraped away all diseased bone. These patients were able to leave the hospital after one week. In cases of chronic sclerotic middle-ear catarrh, on the whole, I do not expect to get good results from the extraction of the ossicles. In some cases the operation is liable to impair the condition of the ear. In chronic purulent cases I think that we must expect little from extraction of the ossicles alone. I have employed Küster's method of opening the attic and antrum with good results.

Dr. FELIX COHN. I wish again to state distinctly that I am not an advocate of the excision of the ossicles and tympanum in aural catarrh, no matter by what method, be it extra-auricular or intra-auricular. I also claim no originality, even in the application, as Stacke himself in the first publication of his method at the International Congress in Berlin mentions as one of the indications its applicability in sclerosis. Bürkner, in his text-book, as well as Schwartz, in his handbook, which has just appeared, both refer to the possibility of excision by this method. So far, however, to my personal knowledge, no cases have been recorded. I have reported only two cases, because, not advocating the excision of the ossicles, after having satisfied myself sufficiently of the applicability of the method, I have not yet found a case that, according to the indications enumerated in the paper which I had the honor of reading before you, warranted success by either method. I believe that there are only a few chronic conditions in the tympanic cavity in which excision of the ossicles will produce permanent results; and unless we decide to operate, not to improve the hearing, but, prophylactically, to prevent a progression of the disease or for cases of insufferable tinnitus, we are at present obliged to limit the operations, so that even an otologist commanding a very large material will not find occasion to operate upon many cases in the course of a limited length of time. Even, however, from the two cases operated upon and my personal knowledge of the technique of Stacke's method in cases of suppurative otitis, I claim

that in suitable cases it would be just as advisable, if not preferable, to operate by the extra-auricular method instead of by the intra-auricular. It is an antiseptic, clean, surgical method. It is comparatively easy and it is safe, safer than the extra-auricular. Although I fully agree with Dr. Holmes that the wholesale excision of ossicles should be condemned—I have tried to preach restriction of indication in my article—I can not see that the objection of Dr. Holmes to this method, that it is painful, can be at all considered. Both methods are surgical operations, and as long as the operation has been shown to be practically safe, an incision a couple of inches larger than we have been accustomed to make in the common Wilde's incision should certainly not deter us from employing a method which may give better results even if it were more painful. The real fact is that the extra-auricular method is painless, because the operation must be done in narcosis, and painless in the after-treatment, since the external wound is sewn up, leaving only a small catgut drain in the lower portion of the wound as a precautionary measure.

Dr. S. S. BISHOP. I do not often insert a drainage tube in the wound of the mastoid operation. The superficial opening is maintained by the pledget of iodoform gauze until the wound heals from the bottom to the opening in the bone. After Stacke's operation I have been obliged to use a tube in the auditory canal for a short time to prevent stenosis. For this purpose a hard-rubber tube was used for one day, followed by a soft-rubber tube for a few days. Since the discussion has turned upon the question of operating for the removal of the drumhead and ossicles for dry catarrh of the middle ear, I will add a few remarks to those which have already been made. I have investigated this subject sufficiently to make me very cautious. Four cases have come to my knowledge, in all of which the results were so disastrous as to deter me from operating for this disease. In one instance the operation was followed by total deafness in the operated ear, suppuration, and vertigo. The suppuration was cured, but the hearing was not regained. Another case was that of a physician who heard his watch 2 inches with the affected ear before the operation, but was troubled with tinnitus. The surgeon who removed his ossicles thought the operation would remove the noises and improve the hearing. On the contrary, when the unhappy man came under my observation he had a suppuration in that ear, seemingly intensified noises, and total deafness. We succeeded in stopping the discharge, and a few weeks ago I found that the drumhead had been entirely reproduced. He still suffers from absolute deafness in the operated ear, and says that the tinnitus appears to be worse, for he can hear nothing else. He traveled about 3,000 miles from home for this operation. Two other cases with similar unfortunate results have been recently reported to me by Dr. Walker, of Denver, and a Kansas City physician, both of whom have promised to furnish me with full reports of these cases. I have had correspondence with other physicians who have operated for dry catarrh, and their experiences, together with my observations of the deplorable conditions that have resulted in the only cases I have ever seen after the procedure, have kept me from trying it. I have often opened the drumhead and removed it without any unpleasant results and with temporary benefit; but the discouraging feature of this operation is the difficulty of preventing a closing of the perforation and regeneration of the membrane. The same occurs after removal of the ossicles. A gentleman has lately consulted me for deafness, saying that an aurist removed his chain of ossicles, but the drumhead would re-form after such operation. The surgeon instructed his patient to return for operation every time the drumhead was reproduced. This put him to considerable inconvenience, as his residence was about 1,000 miles distant from the aurist. But with the hope of finally regaining his hearing he was willing to take these periodical journeys, for he happens to be a very wealthy merchant. In the reports of these operations I have looked to see if such cases were recorded, but they appear to have been overlooked. In ulceration, suppuration, necrosis, etc., I do not hesitate to do these operations, and I take it that every surgeon approves of them as good surgery.

## THE PHONOGRAPH IN THE TREATMENT OF DEAFNESS.

By JOHNSON ELIOT, M.D., of Washington, D. C.

Over a year since my attention was directed to the use of the phonograph as a means of treating chronic catarrhal otitis. Many years since we were advised to exercise the muscles of the tympanum by means of sound waves. This performed through the medium of aural tubes proved to be tedious and was abandoned. It was thought that in the phonograph we had an instrument which would yield the desired results. Though the Edison phonograph had been used for various diagnostic purposes, the credit of introducing it in deafness belongs to Dr. H. F. Gray, of Baltimore, Md., who has recorded some beautiful results. The most of what follows is familiar, but I think best to incorporate it.

Sounds are but a succession of falling waves of air capable of affecting the auditory nerves. Whether they fall regularly or not, they may all be traced to the vibrations of some material body. When a fork is struck the edges are set into vibrations; this vibratory motion is communicated to the air, in which it spreads in waves of condensation and rarefaction having the fork in the center. Where the spherical diffusion is interfered with, as in tubes, the sound is more distinct. Sounds falling upon the diaphragm of a phonograph cause, through its style, a series of minute depression upon a revolving cylinder of wax. Be the sounds composed of many or few vibrations it is analyzed and markings corresponding to the number of vibrations are recorded. From our phonogram thus made we can reproduce the sound time after time. The style drops into the depressions on the cylinder and the diaphragm gives back to the air the vibrations which composed the original sound, though with less intensity. From this we understand that sound is composed of a series of vibrations, and the phonograph is capable of reproducing these and conveying them to the ear. For their effect here we must look toward massage. The vibrations are but a series of taps (tapotement) on the membrana tympani, which are carried by means of the ossicles to the internal ear. The taps cause, as in other parts where massage is used, increase of the venous circulation, freer absorption, prevents and resolves stiffness and atrophy of muscles, and favors the repair of tissues. From this it would seem that the treatment would be successful, but I regret to say my clinical experience does not bear out the claims.

Deafness may be divided generally speaking into two classes, where the middle ear is affected and where the internal ear is at fault. Those affections of the auricle and external meatus are omitted as having no bearing. In the middle ear our most common lesions are catarrhal, generally with a thickened membrana tympani, a sclerosed lining membrane, ankylosis of the ossicles, and depression of the membrane often by contraction of the tensor tympani muscle; the auditory nerve may be but little affected. In these we have the indications of the massage treatment as applied by means of the phonograph. Could we but limit our action to the middle ear or prevent shock to the internal ear, I would fully concur in this belief. To break the false unions of the ossicles and cause absorption of callus thrown out will require sounds of larger volume than the ordinary speaking voice as recorded by the phonograph; in fact these sounds are often not heard by the patient. To persist in the use of such phonograms I consider harmful, as in the endeavor to appreciate the sound one is kept on the *qui vive*, and fatigue of the muscles of the tympanum will ensue. This generally passes, but we know permanent effects may result. In the endeavor to procure sounds of larger volume I had various cylinders made, also making use of musical ones. Intense sounds imply greater amplitude of vibrations, which in the case of the ear means a strong stroke upon the labyrinthine fluids. Normally the labyrinth is protected from

blows and concussions, as, in addition to the yielding which the membranous walls afford, we have a special valve at the fenestra rotunda, the membrana tympani secundaria. This idea is based upon the communication existing between the scala vestibuli and the scala tympani, which is generally admitted.

Physiology teaches that when an impulse is received upon the membrana tympani it is carried by means of the endolymph to its corresponding organ of Corti, which it stimulates, and sends the impulse to the sensorium. This is true, whatever theory of auditory nerve stimulation we accept, as we know the terminal filaments of these nerves are stimulated by variations in the tension of the fluids of the internal ear. If the impulse is great, Corti's organs are protected by the valve action at the round window. This bulging relieves the pressure and prevents overstimulation of the nerve, but in chronic catarrhal otitis the lining membrane of the tympanic cavity is thickened or sclerosed. These changes, involving the membrane at the round window, render it less elastic and less capable of yielding. When this condition is present, we can readily understand that a vibration starting at the footplate of the stapes will fall with augmented force upon the terminal filaments of the auditory nerve. But little is known of the pathology of the special nerve trunks. Overstimulation would cause fatigue and loss of irritability; the sensations would be obtunded as in the case of the olfactory nerves in ozaena. That this is permanent I am unable to say. When deafness depends on labyrinth or nerve changes, can we hope to again bring into activity a nerve by means of massage applied through the ossicles? I do not think it possible; for since phonographic massage will lessen the activity of the auditory nerve, we certainly could not by the same means restore the nerve to its original activity.

In the following cases the deafness depended more especially on changes in the middle ear, and as many are similar I have selected eight from a series of eighteen, all however proving failures.

*Case 2.*—Adult, female; health good; applied for relief of tinnitus aurium of two years' standing, following acute rhinitis; membrane normal but slightly depressed; H. D. R.  $\frac{40}{50}$ , H. D. L.  $\frac{50}{50}$ ; after first treatment tinnitus abated for one day, then returned; ten further treatments given every other day had no influence.

*Case 3.*—Male, aged 38 years; hearing impaired fourteen years; health good; membrane opaque; ankylosis of malleus and incus; adhesion of membrane; history negative; H. D. R.  $\frac{4}{50}$ , H. D. L.  $\frac{7}{50}$ ; tinnitus; treatment every day from June 13 to July 9, then every other day until August 12; the adhesion gave way slightly, but no change was made in audition.

*Case 4.*—Male, 22 years; good health; increasing deafness for four years; membrane opaque; firm ankylosis; nerve in good condition; H. D. R.  $\frac{5}{50}$ , H. D. L.  $\frac{9}{50}$ ; under treatment five months, generally three times weekly; cause stated as repeated colds and tobacco; treatment was of no benefit.

*Case 8.*—Female, aged 40 years; health good; deafness nine years, following typhoid fever; tinnitus; H. D. R.  $\frac{8}{50}$ , H. D. L.  $\frac{10}{50}$ ; membrane lusterless; bone conduction fairly good; ankylosis; treated every third day for four months; audition remained stationary. From a letter received a few days since she states that the phonograph increased her trouble.

*Case 9.*—Female, aged 52 years; seven years' duration; commenced with abscess in left ear; right ear taking on chronic inflammation. There was constant tinnitus and post-nasal catarrh; bone conduction good; treatment about every other day for nearly seven months; H. D. R.  $\frac{4}{50}$ , H. D. L.  $\frac{2}{50}$ ; no change in the hearing distance. While under treatment this patient suffered from an attack of "nervous prostration." As there was no exciting cause, it has been a question with me whether my treatment could have had any influence in its production. During the attack the phonograph was not used.

*Case 11.*—Female, aged 45 years; no cause assigned; duration twenty to twenty-five years; H. D. R.  $\frac{1}{50}$ , H. D. L.  $\frac{0}{50}$ ; tuning fork faintly heard through the bones of the skull; two and a half months' treatment was negative.

*Case 15.*—Male, adult; adhesion of membrane; no nasal or pharyngeal trouble; bone conduction remarkably acute; H. D. R. contact, H. D. L.  $\frac{2}{50}$ . This case I saw but three times and can hardly consider him a patient of mine. He stated that he had been under a five months' treatment in Baltimore just preceding his visit to me and that his hearing decreased from the beginning of the treatment.

*Case 16.*—Adult, male; health good; H. D. R.  $\frac{50}{50}$ ; H. D. L.  $\frac{50}{50}$ ; post-nasal catarrh; Eustachian tubes patent; membrane normal; bone conduction good; applied for relief of tinnitus; treatment for nearly three months proved negative.

## CLINICAL CONTRIBUTION TO THE STUDY OF AURAL SYPHILIS.

By MAX TOEPLITZ, M. D., of New York.

Aural syphilis may be manifested during the secondary and tertiary stages, and some rare cases also even of primary induration of the auricle have been reported. Secondary affections are, as a rule, transmitted through the pharynx and naso-pharynx through the Eustachian tubes into the middle ear, or they appear in the external meatus as condylomata or ulcers. Tertiary syphilis is characterized by chronic inflammations of the periosteum of the labyrinth, with subsequent hyperostosis or exostosis of the petrous bone or of the cavities of the labyrinth leading to stenosis, or even occlusion of the latter. All cases, however, exhibiting syphilitic affections of the labyrinth are due to hereditary or to acquired syphilis of long standing.

The case which I have but recently observed is remarkable by the fact that the labyrinth was affected primarily in the course of a freshly acquired case of syphilis, and that the aural affection began simultaneously with the appearance of roseola.

The patient, a physician, æt. 41, married, of excellent repute and standing, presented himself at the aural department of the New York Ophthalmic and Aural Institute on August 1, 1892, with the complaint only of deafness in the left ear, other symptoms being absent. Otoscopy revealed moderate congestion of Shrapnell's membrane, which seemed to have disappeared on the following day upon application of two leeches to the tragus. Politzerization used for diagnostic purposes did not improve the hearing. Hearing power horologium, A. S. =  $\frac{\text{contact}}{36''}$ , A. D. =  $\frac{18}{36}$ . On August 2, hearing, A. S. =  $\frac{1}{36}$ , improved. August 3, hearing worse; leeches to the mastoid. On the fourth day of observation the right ear, which had been endowed with very acute hearing, had become affected. The examination with tuning forks, which did not give any distinct results in the very beginning as to the relation of bone and air conduction and seemed to be leaning more toward a decrease of bone conduction, revealed on August 4 positive Rinne in both ears, but there existed almost as much bone conduction as air conduction, the former being decidedly decreased. My diagnosis of otitis interna was now fully justifiable, on account of the sudden development of deafness and the great difference of the course of the affection from that of middle otitis.

In order to ascertain the etiology, I questioned the patient about former attacks of syphilis, but with entirely negative result. After repeated inquiries for fresh lesions, the Doctor presented the middle finger of his left hand, which bore in the center a round, hard tumor of the size of a large cherry, representing a genuine primary chancre, contracted during gynecological examinations. Dr. Sigmund Lustgarten confirmed my diagnosis of syphilis. At the same time pharyngeal mucous patches and a beginning roseola were found. Energetic treatment with inunctions of blue ointment were immediately resorted to and injections of pilocarpine were independently made by the patient. The further course of the affections ran as follows:

August 10: Patient experienced a tendency to fall upon rising in the morning, and especially when awakened out of sleep. The walls of the building seemed shaking. He felt once or twice, for a minute, as if he would like to put his hands against the wall, but the phenomenon was not very marked.

August 16: H. P. H. A. U. =  $\frac{\text{contact}}{36}$ . Tuning fork perceived as above. Ordinary conversation is well understood, but the patient has to pay strict attention. Whisper, A. D. =  $\frac{8'}{20'}$ , A. S. =  $\frac{18''}{20'}$ ; conversation, A. D. =  $\frac{10'}{60'}$ , A. S. =  $\frac{6'}{60'}$ .

August 17: Result of examination with tuning forks unchanged; Weber's experiment, T. F. perceived in either side equally well; T. F., both high and low, are perceived when placed upon R. mastoid in A. S., but when R. ear is closed in A. D.; R. E. does not hear all the high notes of the piano above *g'*; R. E. above last *e*; the high notes were perceived as mere taps without the faintest musical sound.

October: In the beginning of October the hearing of A. D. was almost normal; A. S. somewhat improved.

November 23: Whisper, A. S. =  $\frac{15'}{20'}$ ; watch, A. S. —  $\frac{4''}{36''}$ ; conversation, =  $\frac{60'}{60'}$ ; Rinné, A. S., negative.

Weber's experiment: Diapason vortex not perceived in either ear; high and low tuning forks equally well perceived; T. F. placed upon R. mastoid, best perceived in A. S.; hearing for the watch, whisper, tuning fork; conversation was normal in A. D.; musical hearing normal. Mucous patches of the soft palate were not quite healed.

The special features of this case are as follows: (1) The affection of the labyrinth occurred after the appearance of the pharyngeal mucous patches and simultaneously with the appearance of roseala; (2) the aural lesion took place during the secondary stage without attacking the middle ear; (3) the diagnosis of syphilis was made from the ear.

It may be doubted that the affection was located in the labyrinth and in its stead the outer wall of the labyrinth, and more especially the region around the oval window, may be preferred for its location. The entire course of the disease, however, contradicts such an assumption, and also the suddenness of the beginning, the well-nigh entire absence of inflammatory signs in the membrana tympani, the mutual relation of both ears during the attack, the relation of bone conduction and the attack of vertigo; all speak in favor of labyrinthine disease.

The pathological changes produced by the syphilitic poison, which entered the lymphatic and blood current of the labyrinth from the pharynx through the aqueducts and the blood vessels, probably consisted in inflammatory alterations of the membranous portion, the periosteum, and the surrounding lymph of the vestibule, and the first turn of the cochlea, with an increase of cellular elements and hæmorrhages. All these changes disappeared after energetic antisyphilitic treatment. I have looked over the literature of the subject and have not found a similar case of labyrinthine disease due to secondary syphilis in its earliest stage without implicating the middle ear. Politzer\* only mentions in general that in affections of the middle ear due to syphilis the perception of the tuning fork through the skull may be lessened or absent (complication with syphilitic disease of the labyrinth), a fact which essentially supports the diagnosis of specific aural affection when other syphilitic symptoms are present.

## THE PRESENT CONDITION OF OTOTOLOGY IN EUROPE AND THE OPERATION OF EXCISION OF THE OSSICLES IN CHRONIC SUPPURATIVE OR NON-SUPPURATIVE DISEASE OF THE MIDDLE EAR (PROGRESSIVE OR PROLIFEROUS SCLEROSIS), WITH CASES.

By LAWRENCE TURNBULL, M. D., of Philadelphia, Pa.

Having spent the greater part of the years 1892-'93 on the Continent and in Great Britain, I made it my business, as well as pleasure, to compare the present position of otology and note its progress as a special department, as also the character of the representative men who practice it, with that of twenty years ago. I found the advance had been made in several directions. First, a more perfect knowledge of the normal, pathologic and microscopic anatomy of the ear both in men and animals. Second, with this precise knowledge of anatomy there followed a more rational use of therapeutics both in their local and general application. No haphazard probing, but definite operative and mechanical methods of treatment, with perfect illumination by gas or electricity. The old empirical use of the syringe

\* Text-book, first edition (German), p. 693.

with hot alkaline solutions, without looking into the ear, has, we are happy to state, even among general practitioners, entirely disappeared. Almost all are provided with an aural and nasal speculum and some form of mirror with a Politzer air douche. Third, the number of good, scientific, yet practical works on the ear and its diseases are numerous, well illustrated, and can be had at a moderate price. Among these are the works of Pritchard, S. MacNaughton Jones, and Barr, of England; Baratoux, of France, and Hartmann, of Germany; while the more elaborate works of Politzer, Gruber, and Schwartz are prized by the aurist, as they are replete with accounts of improvements in this department brought up to date, and even the English translation of these works has passed through several editions, showing the great demand there exists for this kind of knowledge, not only by the student, but by the active medical man. While in Liverpool we visited the learned Dr. Stone, who is recognized as an authority in that city, and who has done himself great credit by his translation of the admirable work of Politzer, describing the technique of the various instruments and apparatus for the proper dissection both of the normal and pathological ear. Another important union has taken place between the laryngologist, the rhinologist, and the otologist, as without the knowledge of the use of the laryngoscope and the rhinoscope complete diagnosis would not be possible, as most aural maladies, either directly or indirectly, are associated with naso-pharyngeal diseases, and are so described and treated in the more recent works on the ear, throat, and nose. This happy combination was well illustrated in the recent meeting of the British Laryngological and Rhinological Association, in London, which I attended in June, 1892, when papers were read and discussed on these subjects to the advantage and satisfaction of all concerned.

I was also much pleased to find that the sections of otology and laryngology were united at the meeting of the British Medical Association at Nottingham, held from July 26 to 30, 1892, and a large number of interesting papers were read and discussed. There were present a number of distinguished representative men of both departments, among them Profs. von Schrotter and Gruber, of Vienna. Prof. Gruber had the honor of being invited to take a seat on the platform in the general meetings. Prior to my visiting London, Prof. Politzer had made a visit and been the recipient of numerous attentions from both the throat and ear specialists.

While in Great Britain I noticed that great attention was paid to the ventilation of the Eustachian tubes, the removal of adenoid growths, and the general and special treatment of naso-pharyngeal diseases as causing deafness, but not a word was said of operative measures for the relief of chronic suppurative inflammation of the tympanum, now considered of much importance. It is now recognized in the United States as a measure which is absolutely necessary. (Described in Part II of this paper.) First, in chronic aural discharges, especially those from diseased bone or polypi, first proposed and performed by Sexton in 1886. Second, for the relief of vertigo and distressing tinnitus aurium. Third, the cure or relief of deafness, or the prevention of its increase, performed by Schwartz in 1885. Often the slightest improvement in the hearing of the human voice is hailed with delight by the long-suffering deaf person, just as the light admitted by the removal of the cataract, or an iridectomy, is a source of great joy to a sightless patient. Gradually we are improving our methods of diagnosis, the only true method being to discover by the tuning fork whether the seat of the disease is in the middle ear or in the nervous apparatus (inner ear). A series of tuning forks has been devised by Hartmann, of Berlin; his lowest is a C fork registering 128 vibrations per second; the highest a C fork, 4 octaves higher, registering 2,048 vibrations per second. The intervening forks are also tuned to the note C and vary from each other by an octave in the scale. When not supplied with these refined methods, having

only an ordinary tuning fork with a clamp, it is well to remember that a great decrease of boneconduction indicates an implication of the internal ear or nervous apparatus, except in old persons, and in cases of syphilitic bone disease in which there is deposit with thickening. The thanks of every aural surgeon are due to Dr. Sexton, of New York, for his devotion to and careful study of operative measures for the relief of chronic, suppurative, and attic disease, as also non-suppurative inflammation of the tympanum, in the face of great opposition, even in his own city.

Dr. J. Baratoux has performed a few operations in Paris, but in his recent work *Guide Pratique pour le Traitement des Maladies de l'Oreille*, 1892, no mention is made of this mode of treatment. The English have ignored the whole subject, except the operation through the mastoid, by Lane. Our German confrères, who first opposed it at the congress, but are now the strongest advocates for its use, especially Kretschmann, Ludwig, Reinhardt, Grunert, and Kessel, endeavoring to show that the credit of the introduction of the operation for the removal of the malleus and incus from a patient suffering from chronic catarrhal inflammation of the tympanum was due to Kessel in 1877. The operation was without satisfactory results, however, until taken up by Sexton, who proved it not only possible, but advocated the measure and published the first satisfactory results to the world in 1884. It was he who first proposed and performed excision of the membrana tympani and ossicles for the relief and permanent cure of chronic discharges from the ear. I at first was opposed to the operation, but after a consultation and conference with Dr. Sexton I was convinced of its value. At the Jefferson Medical College I made my first successful operation February 5, 1892; since which time I have operated in other cases, and my former assistant, now lecturer on otology, Dr. S. MacCuen Smith, has operated in a large number of cases, both public and private, during my absence in Europe. Some forty of these were clinical cases. In the last edition of the work of Politzer, published in Stuttgart, 1893, on page 276, section 6, "Die Excision des Ganzen Trommelfells und die Extraction des Hammers und Ambouses," he refers to the subject and concludes with a description of the technique of the operation, but gives no opinion of the operation or his cases, nor even states how often he had performed it. He says:

Simrock states that even after complete extirpation of the membrana tympani and hammer a membranous cicatrix forms and fills out the whole opening, which frequently adheres to the opposite wall of the tympanic cavity. Kessel\* claims through the tendinous ring at the posterior circumference of the membrana tympani to have secured a permanent opening. According to the experiments of Schwartze† the cicatrization of the opening results from leaving the limbus cartilage. In the cases operated upon by him a serous secretion or suppurative inflammation followed the operation, the treatment of which required several weeks. The improvement in hearing seems to depend upon whether the vibrating conduction is impeded by the hammer-anvil joint or by the stapes; in the latter case no hearing power is secured. The subjective sounds are often lessened, never aggravated.

Lucae removed the membrane and hammer several times; the anvil in 47 cases, 55 times. The result of the operation was in 9 cases a considerable improvement, in 19 a lesser improvement, in 18 a negative result, and in 7 cases an aggravation.

Lucae‡ considers the operation in clinical cases as without danger, but the result so unsatisfactory as to make it advisable to set the procedure aside, pending the establishment of more precise indications.

The excision of the whole membrana tympani together with the hammer, or even hammer and anvil, has been more recently advocated by Sexton§ on the strength of a considerable number of favorable results at his hands. According to Sexton the operation is indicated in a dry middle-ear catarrh, with a progressive tendency, especially when accompanied by tinnitus and vertigo and when the previous local treatment (catheterism, etc.) has been fruitless. The earlier the operation the better the results.

While in Brussels I called to see Dr. Charles Delstanche, the president of the recent Otological Congress held in that city. He contributed by his generous hospitality very much to the happiness and comfort of those who attended it. He stated that his patients still continue to derive much benefit from the use of the massage to the auditory canal and membrana tympani, and uses his condensing syringe and also pure liquid vaseline, or associated with iodoform, especially in subacute cases of otitis media.\*

I returned again to Paris in May, 1893, and visited the distinguished otologist, Dr. Lowenberg, president of the Paris Otological Society. I found that he held with great tenacity to the use of the silver Eustachian catheter on account of the risk of infection. These catheters are of three sizes, and in a pamphlet given to us he describes a new method of catheterization of the Eustachian tube, as follows: He states the principal difficulty during the first stage of the operation is the horizontal deviation of the septum. This he obviates by using half of a nasal speculum, so as to guide the catheter and press the septum aside. During the second stage, when the point of the instrument leaves the nasal cavity, it is difficult to tell when we are in front of the pharyngeal orifice of the Eustachian tube. When he thinks that his catheter has arrived at the end of the post-nasal cavity he orders the patient to swallow. If the instrument has not yet passed the nasal cavity the hand holding the instrument feels no shock, but if the instrument has passed into the pharyngeal cavity the soft palate when contracting pushes it sometimes into the tube, or at least displaces it, which movement can be seen and is also felt by the hand. The correct distance once determined, it will be useful to mark it in the instrument. He employs a piece of new rubber tubing for each individual patient to tip the Politzer bag, and inflates the air charged with chloroform vapor. He also adheres to the syringe for the removal of epithelium, scales, etc., seldom employing the probe. He also employs the galvanic cautery for the removal of the polypi and polypoid-like growths. He seldom employs ointments. In this he differs from Politzer, depending chiefly upon alcohol and boracic acid; and he still believes in the special microbes to be found in the pus of suppurative otitis media, as also in furuncles. He seldom operates for diseased mastoid, believing in the use of local applications in the early stage, leaden tubes for ice water and subsequent persistent and careful syringing with Hartmann's intertympanic catheter. He has as yet not employed operative measures for the relief of chronic suppurative and non-suppurative inflammation of the tympanum, waiting, as he states, for further trials.

On my visit to Rome I found great activity in preparation for the International Congress of September, 1893,† and numerous valuable papers will be read in the section of Otology by the distinguished men of that city, more especially Gadnago and De Rossii, who have devoted much labor and careful research to the obscure diseases of the nervous apparatus of the internal ear.

Of the whole number (154) of cases operated upon by my assistant, S. MacCuen Smith, at several of which I was present and assisted him, the youngest was 4 and the oldest 81. The number which either had a continuous or recurrent discharge was 85.

---

\* In passing it will be interesting to some of my confrères to know that he has since informed me by note that the next Otological Congress is postponed until 1895.

† Which has been postponed to April, 1894, on account of the cholera.

In the foregoing list of 154 operations it will be found that from cases 15 to 84 inclusive we record 691 patients presenting the non-suppurative variety of middle-ear disease. Many of these patients suffered from distressing tinnitus; severe pain, staggering, vertigo, and marked impairment of hearing, while others complained of one or more of these same symptoms in a much less degree. Their ages range from 21 to 81 years. The time in which the patients suffered from one or more of these symptoms varies from two to forty years, while the time elapsing since the date of operation is from three months to four years. The improvement in tinnitus and vertigo has been in many cases most striking and satisfactory, notwithstanding the little hope that could be offered for their relief in some of the cases before operation. The probable improvement of hearing in this class of cases is of course not marked by so many favorable possibilities as in the suppurative variety and yet a perusal of the carefully recorded results will, we think, be convincing that the operation in selected cases is now justifiably demanded.

#### PART SECOND.

In chronic suppurative disease of the middle ear, after all ordinary measures have failed, the excision of the membrana tympani and ossicles is resorted to for relief or cure of carious or necrosed bone or diseased tissues, causing mechanical obstruction to the entrance of sound, and is now a well-established rule of practice as well as a decided advance in aural surgery. In non-suppurative or chronic middle-ear inflammation the operation has received the term "otosclerectomy" (*οὖς*, *ὠτός*, ear; *σκληρός*, hard; *ἐκτόμη*, excision), or the surgical removal of all or part of the sclerosed and ankylosed conductors of sound. The operation has received the sanction of the majority of the aurists of the United States and many in Germany for properly selected cases. Now and then we meet with cases of such failures as occur with our best surgeons in the best diagnosed and selected cases. "To err is human," etc., and in our experience of many years in the practice of the profession we have witnessed some errors and have received authentic reports of sad results in general surgery from others. Not only do they occur in the hands of the tyro, but in those of professors and hospital surgeons of our cities. In properly selected cases of non-suppurative or chronic middle-ear inflammation our success has been good, when we find a patient with the obstruction anywhere between the thickening and adhesions of the membrana tympani or ankylosis of the malleus with the incus. It is almost always necessary to perform a preliminary operation by a removal of an oval piece of the drum with the malleus. When we find that this opening improves the hearing or relieves the tinnitus and vertigo, we then complete the operation by removing the incus. If there be any dry, progressive sclerosis affecting the stapes, it has been advised to make a long incision in the membrana tympani posterior to the malleus, and to use traction on the incudo-stapedial joint. If these are not effectual in removing the annoying symptoms, then it will be safe to resort to the full operation, i. e., excision of the membrana tympani and ossicles. In our hands even sclerosis has been stopped by the operation. See case which stood the test of two years, as follows:

The most recent one was a lady of 38 years. She was profoundly deaf, only hearing the watch, of 60 inches, on close contact on either ear. There was pain and great tinnitus, with vertigo. Both ears were operated upon May 22, 1892. The left ear first, the right ear soon after, as at first she did not experience much benefit. The parts continued so patulous that she breathed through her Eustachian tube. In May, 1893, her hearing had improved to 8 inches for the watch on the right and 4½ inches on the left. She can hear an ordinary voice, by first calling her attention to it, at 25 feet, and is no longer considered very deaf by her friends. The progress in this case was very slow, being almost one year before decided improvement took place.

The following is a much more satisfactory case:

Excision of the membrana tympani and handle of malleus in otitis media catarrhalis chronica, with improvement of hearing and removal of the tinnitus and vertigo: E. H. K., aged 46, a daughter of one of our deceased county judges, was left dependent upon her own exertions for a livelihood. When she presented herself, June 9, 1891, at our office for treatment she was profoundly deaf from otitis media catarrhalis chronica of many years' duration. She had also suffered from chronic rhinitis, with nasal hypertrophies, all of which had been removed and everything done for her without improving her hearing. On testing her hearing by watch, of 60 inches, it was not heard on close contact on the right ear, and only 3 inches on the left.

Miss E. H. K., *status præsens*, June 18, 1891: Right ear, membrana tympani thickened; the short process prominent; the handle attached to the promontory and the whole malleus was twisted on its axis (torquirt) Gruber; the air enters the tympanum; H. W. close (pressed contact); tuning fork, full C; Reiner's test shows the auditory nerve normal; bone conduction good; tinnitus (from pressure), escaping steam, hissing, and roaring. Left ear the better looking, taking all points in topography of the membrana tympani, etc.; conditions the same as in fellow-ear; air enters the tympanum full and well; but one section (posterior and superior) moves from autoinflation; H. W. = 3 inches, Reiner's test negative; the auditory canal was relaxed and dry, with a general congestive condition; bled on rough contact of cotton. A radical operation was proposed, excision of the membrana tympani and malleus; and she consented, as she had great difficulty in being understood in her business.

After suitable preparation the patient was admitted into the woman's surgical ward at the Jefferson Medical College Hospital on Friday, February 5, 1892. She was operated upon on Saturday, the 6th, Dr. Eads, one of the surgical assistants, administering the ether by carefully dropping it on a folded towel until there had been employed some 4 ounces, but she was not profoundly unconscious. We then directed her to be given a few whiffs of chloroform, which had the desired effect, but in a few seconds respiration became embarrassed, and the chloroform was withdrawn; artificial respiration was performed, and after prompt recovery the ether was again resumed and the operation performed. The first difficulty was the great relaxation of the lining membrane of the auditory canal, which was pushed before the Gruber speculum. A bivalve was then tried with no better results. A large-sized ordinary Politzer speculum was then employed with the illumination of the electric light. Another difficulty in her case was that after performing the double incision the canal was filled with blood, which was very much in the way during the whole operation. In cutting around the malleo-incudal joint found it very firmly ankylosed, so that it could not be removed by a strong pair of forceps; so, after using all the force considered justifiable, Dr. Smith, who assisted me, tried to remove it, but he had no better success, although he found the section complete all around the membrana tympani, and also the double incision running up to the membrana flaccida. After removing the membrana and handle and part of the malleus and cleansing the parts and blowing iodoform powder into the canal, plugging it with iodoform cotton, the patient was removed from the operating room to the ward. She had considerable nausea from the anæsthetic, but had no bad symptoms, and was able to leave the ward on the ninth day after the operation, greatly improved in hearing, being able to hear with that ear when the other was closed.

On examination ten days later she stated that everything sounded loud to her. She also heard the watch half an inch from the ear which before she could not hear on close contact. The following is her own statement, she being well educated and intelligent: "Am both pleased and surprised with the result of the operation, for although I was not very sanguine of deriving much benefit from it, at least I would not let myself hope too much, fearing a disappointment; yet I was willing to try. From the very first day after the operation I found an improvement. Voices at the other side of the room were loud and unnatural, but I could not distinguish the words. The footsteps which before seemed to move noiselessly along the bare floors, now seemed like the tread of heavy shoes. I can now hear the voice and speech given in an ordinary tone and without being very near the speaker. The noises of wagons and cars in the street are very loud and sound as if the ground was hollow. All sounds and voices seem loud and unnatural, excepting music, which has lost none of its sweetness. All my friends are surprised and pleased with the improvement in my hearing, and say it is no effort to make me hear them now. This is all without my ear being entirely healed, and filled with cotton wool. I am now waiting to hear what improvement I will find in being able to hear a sermon or address in public. I have tried to give you a very cor-

rect account. I have a sound in my ear like puffing of steam, always worse after coming upstairs, but sometimes it is so faint that I forget it."

The patient presented herself on twelfth day, and we removed considerable dried blood. Tested her hearing and found her progressing most favorably. Again, on February 17, my patient reported as follows: "Hearing continues good and the harsh sounds are disappearing." Tested her hearing in ordinary conversation, with her face turned from me, and she heard me distinctly at a distance of 13 feet.

Two weeks later she reports: "Yesterday was the first test I have made of my hearing, since the operation, in church, and it was a complete surprise to me, for I had never imagined that I should find such great improvement. I had no difficulty in hearing the lessons read, and in fact all of the service, and I was able to join in myself, and that is what I have not been able to do for a great many years—fifteen or sixteen I think—and the great volume of sound that came from the organ almost overwhelmed me, I was going to say—perhaps that is almost too strong a word—yet I have often been in doubt whether the organ was being played at all, it would be so indistinct at times, and yesterday the difference was so great. I find a great improvement in many ways. I get along much better at work, and my friends do not have to strain their voices to make me hear."

One month and five days after the operation, since her last visit, she reports: "Have had some pain in the ear, but on blowing the nose forcibly some blood passed, and the pain disappeared with no return since. Visited a friend in the country on Sunday, who stated that it was like a revelation, the restoration of my hearing. At a business meeting I was able to hear all that was going on, when formerly I heard not a word."\*

Two years after the operation, June, 1893, hearing continues perfect in the ear operated upon; new membrane formed has been examined by Dr. S. MacCuen Smith, Dr. C. S. Turnbull, and Dr. C. M. Thomas; all confirm the good results in her case.

In proliferous disease of the middle ear, and when all ordinary and extraordinary measures, as massage, vaseline, Eustachian bougie and catheter, vibratory treatment, etc., have failed, we are fully justified in opening the drum, and excising the head of or the entire malleus, but it has not always been found necessary to remove the incus and stapes. In cases of severe pain in the ear of an obscure nature, with a dreadful feeling of pressure, cases of which have been seen at the aural clinic, much relief of a permanent character has been afforded the patients by opening the drum and disarticulating the malleus. On examination there has been found diseased bony structure which giving no other indication on the surface. We have found similar disease in the mastoid region, where in two cases an opening was found in the bone large enough to admit the tip of the forefinger. We have never, as yet, known of a death from this operation, but cases have been reported where the hearing power has been made worse. Cases accompanied with atrophy or paralysis of the auditory nerve should not be operated upon. Again, great care must be taken not to injure the Fallopian canal with the incus hook. Children can be operated upon, and even old men have had their hearing restored for ordinary conversation, also experiencing great relief from tinnitus and vertigo. As a matter of course, the older the individual, the less chance of restoration to good hearing. Yet cases aged 60 and even 81 years have been operated upon with good success.

We are all liable to accidents, yet much can be done to prevent them by great care in our manipulations in so limited a space as we have to operate. The use of antisepsis, a good electric light, and a proper clip for a lens on the back of the forehead mirror; this is necessary for presbyopes.

The mobilization and extraction of the stapes was first proposed by Ricardo Botey (Berlin Congress, 1890) and modified and performed by Miot and Boucheron. An incision was made on the outer periphery and the stapes was extracted by a Palet hook. Kessel and Botey employed extraction through the fenestra ovalis in

---

\* Progress of Otology, Annals of Ophthalmology and Otology, April 1, 1892.

anched and fixed stapes. Still later, C. L. Jack\* reported 16 cases; 5 for chronic middle-ear catarrh, in which there was a remarkable improvement in a number of the cases. Then we have the synechotomy, or section of the stapes suggested by Schwartze and published in the transactions of the congress at Basle. (In Politzer's work are figured the instruments for the performance of these operations, pp. 273-275; Figs. 144, 145, and a careful description of the operation.) The most recent report on the removal of the stapes is by Clarence J. Blake (Boston)† of 4 cases operated upon under a solution of cocaine. His results have not been very encouraging; 2 were slightly improved, and in 2 there was no improvement. The operation for excision of the stapes has only been performed in a very few cases in Philadelphia, owing to the prolonged staggering vertigo which followed them.

Schwartze's contraindications to operation for removal of the drumhead, hammer, and anvil: (1) Excessive deafness so great as to require shouting into the ear of the patient. (2) When inflammation of the middle ear produces not even temporary improvement in hearing or tinnitus. (3) When puncture of the drum head improves neither tinnitus nor hearing, never do a double operation and do the operation only in the worst ear. Operations should only be performed under these conditions. Our own conclusions are as follows: When a patient is so deaf as not to hear the voice close to the ear or a watch of 60 inches applied in contact, we would reject such as unfitted for the radical operation, but the preliminary one can be performed. If the suppurative process has continued for a very long period, especially in a scrofulous or consumptive individual, it is best to give a guarded opinion of the success of the operation, as structural lesions of the internal ear are apt to occur.

The demonstrations shown by Prof. Politzer, besides their scientific interest, aid us in understanding why in many cases our therapeutic efforts are not crowned with success. You know, gentlemen, that in recent years various attempts have been made to accomplish the extraction of the stapes for the purpose of diminishing the degree of deafness. As a matter of course, such an operation is only possible as long as the affection has not produced a condition of ankylosis. When the plate of the stapes is once fixed to the fenestra ovalis, or even partially fixed, an operation becomes impossible, for the arch of the stapes would break off under the least traction. But even should our operation appear to bring immediate relief we can hardly hope for a permanent result in all cases, if we bear in mind the anatomical changes which we have observed in the specimens shown by Prof. Politzer. As we have seen that the osseous proliferation originates in the capsule, is progressive, and extends toward the oval window, almost invariably producing complete occlusion of the fenestra, even an early extraction of the stapes would hinder the progress of the disease in the form of ankylosis here described.

#### DISCUSSION.

Dr. M. THORNER. The favorable results obtained by Dr. Turnbull in a number of cases of removal of the membrana tympani and some of the ossicles are certainly very remarkable. I am inclined to think that in his cases, as well as in those reported by some other gentlemen, conditions prevailed more favorable to obtaining good results than in cases reported by some observers who greatly disfavor these operations. I think that we may expect, in cases of simple adhesions,

---

\* Transactions American Otological Society, 1892.

† Archives of Otology, April, 1893, p. 196.

better results than in those of complete ankylosis. If the malleus has been removed, it appears to be rather risky to leave the incus where it possibly might do harm, while its presence can not aid any longer in the mechanism of the sound-transmitting apparatus. As to the removal of the stapes, there is at present scarcely enough evidence to formulate distinct indications for this operation. But it stands to reason, especially if we consider the light thrown upon this question by yesterday's demonstrations of Prof. Politzer, that in a great majority of cases we can not expect to obtain any permanent results by the operation of stapedectomy. I would like to ask Dr. Turnbull in what position he places his patient during the operation. May not the position, either the sitting or half reclining, have been responsible for the embarrassment of respiration, observed in the one patient, as soon as chloroform was given?

Dr. HOBBY. Is it not possible that many of the failures in operations upon the middle ear are due to labyrinthine disease having been previously developed?

Dr. MALONEY. I would like to ask Dr. Turnbull whether the two successful cases reported in the paper read by him represented the success obtained in the entire number of operations named by him in the first part of his paper? My method of treatment compels me to admit the necessity for excision of the membrana and ossicles only in cases showing caries, and not as a means of improving the hearing. The limited success following this operation for improving audition I think sustains me in my view.

Dr. TURNBULL. In reply to the question of the secretary, I am not sure of the removal of the incus, and therefore did not state that it was removed. I always operate by placing the patient on a bed or lounge on the side. A number of chronic cases are reported in Dr. Smith's table operated at the clinic of the Jefferson Medical College Hospital.

### FOCUSING EAR TRUMPET.

By EDMUND D. SPEAR, M. D.

The large number of cases of incurable diseases of the ear, accompanied by deafness for conversational tones, makes it necessary for the aurist to prescribe some form of acoustic apparatus as an aid to hearing. The unsatisfactory character of the ordinary mechanical aids is, perhaps, the cause of the negligence of aurists in regard to this matter. In Burnett's recently published *System of Diseases of the Ear, Nose, and Throat* an article on "Acoustic aid to the deaf" will be found, in which I make suggestions regarding the use of instruments for patients with defective hearing, and I shall quote some of them in this paper.

The importance of this is not appreciated by aurists as it should be, partly, perhaps, from the fear that the impression might be given that when artificial aids are advised the prognosis is no longer favorable and the case likely to be considered incurable. This fear, together with the general antipathy to the use of instruments, continues to prevent encouragement in their use, and may effectively hinder the scientific study of very interesting acoustic phenomena for the development of this department of otological research. To paraphrase the words of an eminent writer, "If it were not that the science of acoustics is one of the least perfect branches of human knowledge, and its practical application certainly the least understood, it would be easy to explain the principles on which perfect ear trumpets should be made."

Acousticians and aurists have, up to the present time, failed to furnish any single instrument to suit all cases, or indeed any satisfactory apparatus or mechanical means (besides the so-called artificial membranes) for restoring the function of hearing. It is true that a limited number of deaf patients find that some particular device serves to improve their hearing for certain sounds and individual voices, but there is no instrument which can be varied in shape so as to change with the varying character of the sounds desired to be heard.

SCHEME OF FOCUSING EAR TRUMPET.

FOCUSING EAR TRUMPET.

FOCUSING EAR TRUMPET.

A few principles for guidance in the choice of proper instruments will be here given. The size, shape, and length of each tube, as well as the condition of its interior surfaces, its mouthpiece, and ear tip, are to be first examined and compared with those of all kinds obtainable. The size of the internal bore of a tube is of prime importance, as every aurist knows by experience with his "otoscope," which is usually made of flexible rubber tubing fitted at each end with ear tips. A comparison of tubes of different caliber, though fitted with the same ear tips and of equal length, will quickly show that tubes are resonators for the various tones, and that the same sounds heard through the different tubes appear much varied in character. Cone-shaped tubes without breaks or seams within are best formed to convey the sound waves to the ear.

Of the score of forms of ear trumpets offered for the use of the deaf by surgical-instrument dealers, but three or four appear to be constructed with a view to secure the best results with the least expenditure of material. In order to meet a demand for small instruments makers have been led to sacrifice utility for size, and on this account have fallen into error.

The ear trumpets which give the most satisfaction are those made on proper acoustical principles without reference to size. These combine the reflecting parabola with the cone-shaped conducting tubes. All the ordinary ear trumpets consist of large horns with wide extremities, tapering with more or less varied curves or with frustra of cones to the small ends, which are fitted with ear tips intended to fit into the auditory canal.

A cone-shaped tube tapering to a point, and with one of its sides partially cut away, is the best kind of instrument for the use of those partially deaf. The cut in the side, as now made, is of service in forming shorter columns of air in the tube, which serve as resonators for tones of high pitch (partials of tones), thus giving a more serviceable instrument than one formed from a plain cone.

Research and experiment in applied acoustics will accomplish what I hope to open the way to by the presentation of instruments which in a measure fulfill indications, and the aurists, to whom this work belongs, must undoubtedly profit by the results.

To illustrate my improved manner of condensing sound waves I shall present to the section two forms of instrument. Strictly speaking the word "focusing" can be applied as descriptive of the manner in which the sound waves are condensed in referring to what takes place in one only of these forms, though the result arrived at is practically the same in both. In the long axis of a metal reflector, whose sides are parabolic, a short, hollow, metal cone is placed with its large end directed inward. These are relatively so fitted that the cone can be adjusted for the various focal points of the parabolic reflector by being moved nearer to or farther from the apex of the reflector. To a cone-shaped tube tapering to a point and of a length to correspond with the wave lengths of tones whose pitch is below C, is fitted a small tube within which another tube is made to slide. To this latter tube a small hollow cone is fastened at one end; a short, curved tube is fitted at the other end. This comprises the portable form. By varying the length of the air columns within the cone and adjusting at different points a considerable variation in perception of tones is produced.

### AN IMPROVED MIDDLE-EAR POWDER BLOWER.

By R. D. BARRET, B. S., M. D., of St. Louis, Mo.,

*Clinical Assistant to the Department of Diseases of the Ear of the Missouri Medical College.*

The little instrument I wish to describe to you as briefly, yet as clearly as possible, was designed primarily for the purpose of applying directly to the diseased parts any of the various antiseptic powders so often indicated in the treatment of those cases of chronic suppurative inflammation of the attic space, in addition to the inflammatory process going on in the atrium. But it has proved to be for me the most convenient and perfect universal powder blower I have found

as yet, and I hope it may be equally as useful to others in every respect. Its three component parts are the canula, the receptacle for the powder, and the rubber hand bulb. The canula is similar to that of the Blake middle-ear syringe, 3 inches long, one-sixteenth of an inch in diameter, and has an upward curved extremity to direct the powder into the attic. A second canula with a straight point will add greatly to the range of usefulness of the instrument. The receptacle for the powder is a metal bulb an inch in diameter. From it projects a tube about three-fourths of an inch in length, and to the end of this the canula is attached.

At a point directly opposite is a short nipple, over which fits the rubber tube leading to the air bag. Over the opening of this nipple within the powder receptacle is soldered a wire screen with a mesh so fine that the finest powder will not pass through it unless rubbed, but still it does not interfere materially with the force of the air current. This screen prevents the powder from falling or being drawn into the rubber bulb. The powder receptacle is opened for filling by unscrewing a small segment of it, the center of which is the point of attachment of the canula. The base of this tube is encircled by a milled-edged band to prevent the annoying slipping of the fingers so frequently experienced with such instruments. To the under side of the largest part of this receptacle is fastened a handle in the shape of a loop through which the thumb is slipped in using the blower. The air bulb is the ordinary rubber bulb used for the same purpose on other instruments. The tube leading to it should not be over 3 inches long, and for one with a small hand even that is too long. In using the instrument the thumb is slipped into the handle from behind, the powder receptacle resting on the top of the thumb between the nail and the knuckle, the first finger steadying it by pressing the handle against the ball of the thumb, the rubber tube passing to the outer side of the thumb—not between it and the first finger—and the air bulb then falls naturally into the palm of the hand, when a very slight pressure upon it by the two or three free fingers puffs out the powder. A too forcible compression of the bulb simply blows the powder around the receptacle, but the least bit of force will puff it out readily. The canula is bent at an angle of  $130^{\circ}$  from the body of the instrument, hence it is all that is in the line of vision.

The right hand manages the instrument perfectly, leaving the left free to hold the speculum or for any other manipulation that may be necessary. The cannula and powder receptacle are nickel-plated, can be easily and quickly separated, cleaned, etc., and there is nothing about the instrument to break or get out of order every few days.

My sincere thanks are due to the Mellier Surgical Instrument Company of this city for the careful and skillful manner in which they carried out my idea and the perfect instrument they produced.

---

## ADENOIDS A CONTRIBUTIVE FACTOR IN AURAL AFFECTIONS.

By M. D. LEDERMAN, M. D.,

*Assistant Surgeon, Manhattan Eye and Ear Hospital; Instructor in Laryngology and Rhinology, New York Polyclinic; Assistant Laryngologist and Otologist, Mount Sinai Hospital Dispensary.*

Although hesitating before offering an abbreviated paper upon a subject which has generated such universal discussion, the continued appearance of neglected cases permits the expression of pleasant results observed after the removal of this frequent causation of middle-ear disease, especially in children. Realizing that this subject has already commanded the attention of some of my auditors, I console myself with the thought that this field of medicine has been so thoroughly

AN IMPROVED MIDDLE EAR POWDER BLOWER.

cultivated it would seem impossible to make an absolute discovery. However, I trust you will bear with me, in the hope that there may be a few among those present who have not given this cause its deserved recognition.

When we consider the percentage of ear diseases prevalent in early life it, behooves us to carefully investigate the observation of clinical experience and test the virtues of its information. It is indeed gratifying to reëcho the statements of others interested in this topic, and to conscientiously testify to the delightful benefits derived from the ablation of the hypertrophied lymphoid tissue in the post-nasal space, especially in cases of suppurative otitis chronica. Although appreciating the impression produced in offering statistics upon any given subject, I will not tire you with them, but with your kind indulgence will give later the history of two or three cases that demonstrate these few remarks.

In attempting to ascertain the immediate influence which the hypertrophied pharyngeal tonsil has upon ear disease we are confronted with numerous proposed theories.

Before giving any of these in detail, I briefly quote the statements of some authorities on the disturbing effects of so-called "adenoids" upon the sense of audition. Woakes\* expresses his experience in these words:

Interference with the organs of hearing, inducing more or less deafness, is the most frequent and to my mind the most important of the direct lesions resulting from the disease. Not more than 5 per cent of my cases have escaped this complication.

Beverly Robinson† mentions the observations of Dr. Swinburne, who states that "in a large proportion, indeed in all cases, of adenoid vegetations the ears were found diseased." Again, Dr. Robinson adds that "other observers have described the great frequency of aural complications in cases of adenoid vegetations." Under the symptomatology of hypertrophy of the pharyngeal tonsil, Dr. Bosworth's‡ experience is so clearly expressed, I can not offer a more weighty thought than to quote verbatim from his valuable work:

Probably no symptom of the disease possesses greater importance or requires more thorough appreciation and study than that of ear complications, occurring, as they do, early in life and at a time when their prompt recognition only may save the patient from permanent loss of this important faculty.

In referring to cases of total deafness in children due to this lymphoid swelling, Lavrand, § of Lille, considered the growth to be a cause of deaf-mutism, and thought that their removal would act as a possible cure of the latter affection. If we believe that this pitiable condition is contingent upon pharyngeal vegetations, their predominating influence is truly amazing. In a very interesting and instructive brochure || upon Lymphoid Growths in the Vault of the Pharynx, Dr. T. R. French informs us that deafness as a complication of this disease occurs in more than half the cases. With such statements before us we can not lay too much stress upon the immediate relationship the nose and naso-pharynx bear to aural disturbances.

My experience in clinical and private practice certainly proves the immediate influence this disease has upon the production of deafness, be it a catarrhal or suppurative manifestation. I have watched the progress of young patients under the routine treatment of syringing, peroxide of hydrogen drops, with boric-acid insufflations, and though the suppuration ceases for the time the patients would often return with another outbreak. These recurring attacks were promptly overcome by ridding the pharynx of its irritating occupant. We should never consider an

\* Woakes, Post-Nasal Catarrh.

† Beverly Robinson, Treatise on Nasal Catarrh and Allied Diseases.

‡ Bosworth, Diseases of the Nose and Throat, Vol. 1.

§ Lavrand, Annual of the Universal Medical Sciences, Vol. 4, 1890.

|| Paper read before the Kings County Medical Society, August 18, 1893.

examination of a patient with ear difficulty completed until the nose and nasopharynx have been thoroughly inspected. In children we should never hesitate to bring to our aid the proverbial eye at the end of the finger. It is not exaggerating to assert that the majority of running ears in children, together with the depressed condition of their general health, is the consequence of this often-neglected factor. It is not unusual to diagnose the presence of these growths by the child's facial expression alone. The senile appearance of the young one, the drooping eyelids, together with the open mouth, are indicative of the post-nasal obstruction.

As to the theories suggested in the causation of ear disease by these growths, Bosworth supposes the trouble to be due to an interference with the renewal of air in the middle chamber. Any cause which interferes with free nasal respiration, if continued sufficiently long, is liable to produce impaired hearing by creating a stagnation and rarefaction of air in the pharyngeal vault. The free action of the levator palati muscles is hindered by the hypertrophied tissue, thus preventing their compensating action. A catarrhal process is incited by this rarefaction, an hyperæmia and its consequences appearing in prompt succession. Lowenberg concludes that the inflammation is a direct continuation of the pharyngeal involvement. Blake reasons the result to be due to a passive hyperæmia of the middle ear, by interference with the return circulation, owing to the pressure exerted by the post-nasal growths upon the pharyngeal veins. This seems quite a plausible theory, and we can readily imagine that some such effect may be the result if the blood current of the neighboring tissues is materially obstructed.

My views incline toward the supposition of some disturbance of the circulatory function. There can be no doubt that the presence of this foreign element influences the blood supply, thus exciting a congestion of the local tissues, and possibly affecting the vasomotor system of the middle ear as well, thereby giving rise to an inflammatory process. We are yet in the shadow of a revelation which I earnestly hope will soon illuminate the present obscurity.

In dwelling upon the immediate relation of this factor in the production of aural complication, it would be unpardonable had I omitted mentioning the deleterious influence that nasal stenosis has upon the organ of hearing. Suffice it to state that in the majority if not in all cases of otitis media catarrhalis chronica in which there exist some obstructing lesion in the nose, we may sincerely expect to improve the patient's hearing by removing the barrier to normal respiration, thus allowing the necessary aeration of the Eustachian tube and middle ear. The proportion of children under 10 years of age that are subject to adenoid growths is so large that I anticipate their presence in almost all cases of middle-ear suppuration, particularly if it be of a chronic nature. The happy results obtained from the thorough removal of the pharyngeal obstruction in such cases permits me to cheerfully promise a speedy relief from the offensive discharge and an improvement in the hearing distance, not overlooking the beneficial effects upon the general health of the patient.

Very briefly I mention the history of a few cases, in one of which the discharge ceased surprisingly soon after the surgical treatment:

*Case 1.*—Nettie G., 3 years of age, well nourished; mother noticed that the child experienced difficulty in breathing; was restless at night; tossing about in sleep, snoring loudly; lips were parched and covered with a deposit of dried secretion in the morning; in short, a mouth-breather. The little one had attacks of fever off and on, in one of which an acute suppurative otitis media developed. There was some pain before pus showed itself, but it was not distressing. The ear was treated by the family physician with hot-water douches and boric-acid insufflations. The suppuration ceased for two months, then reappeared with acute symptoms. The same treatment was continued, with a cessation of the discharge. With the next appearance of the difficulty the patient came under my care. The history being so pronounced, and the expression of the child's face being quite typical, I immediately examined for adenoids, and found the pharyngeal vault

completely filled. The growths were removed under an anæsthetic by means of the curette. On the fourth day following the operation no sign of suppuration was visible. Peroxide of hydrogen failed to reveal any pus. Until the present time (almost a year since the operation) the child has had no reëpearance of her trouble. Her hearing has improved considerably, as shown by the voice test. At time of operation watch and finger-nail tests were not satisfactory. The child when last seen affirmed to the watch test at 3 feet and heard the voice in the usual tone. The parents noticed the improvement in hearing three weeks after the operative treatment.

*Case 2.*—The pleasant effect of the surgical treatment in this particular case makes the history unusually interesting. I am indebted to Dr. Alvarez for the following history: J. H., aged 7 years. Mother lived in Florida, and while pregnant with this child had an attack of chills and fever. The child was born in New York. Three months after his appearance into the world the infant was also attacked with chills and fever. This lasted for a week or ten days, and was treated by the family physician as malaria. Ever since the boy has had periodical fevers every two or three months. Dr. Alvarez first saw the patient in the spring of 1891. Doubting these attacks to be malarial, yet unable to ascertain their origin, he recommended a change of climate. The child spent the summer in the Catskill Mountains, but no improvement was noticed. The temperature in these febrile attacks never arose above 101°. In August, 1892, the young lad became more ill than usual, and Dr. A. discovered that the faucial tonsils were markedly hypertrophied and adenoid growths were present in abundance. He then associated the periodical fevers with his discovery. In November following the little fellow became the victim of an acute otitis media suppurativa of both ears, which failed to get well under the usual treatment. This ear continued discharging until February, 1893, when I was requested to see the patient. The removal of both tonsils and adenoids was at once performed. The running ears ceased to flow at the end of two weeks, and up to the present time the periodical fevers have not returned.

Through the kindness of Dr. Gruening, I briefly offer the history of an interesting case which proves the direct effect this common affection has upon aural disease. A boy 5 years of age had two attacks of double-sided suppuration, complicated with mastoid disease, and at each attack the doctor was obliged to operate upon both mastoids. After the removal of the adenoid vegetations the patient rapidly recovered, and has had no attack since that time. Dr. Gruening expresses his experience in the following words:

I have repeatedly observed cases of otitis media purulenta which, though yielding temporarily to local treatment, had a tendency to recur, and that the tendency ceased when the adenoids had been removed. These and other cases lead me to believe that adenoid vegetations are a causative factor in purulent disease of the middle ear and the mastoid.

Such observation is conclusive evidence of the important relation that this exciting factor bears to middle-ear disease. True, we sometimes find suppurative cases in children in which the adenoids are wanting, but they are indeed very few. It is not in the realm of this brief paper to dwell upon the methods employed in the removal of these growths, but will state that I have found the modified Gottstein's heart-shaped curette, together with the use of Lowenberg's post-nasal forceps, improved by Dr. Gleitsman, of most service. The continued employment of a favorite instrument leads one to become too greatly impressed with its superiority, and we are apt to overlook the good qualities of others. It is therefore necessary to test the merits of the modern modifications and by personal experience select the most serviceable. Dame Nature has considerably supplied some of my esteemed colleagues with strong finger nails, which have been cultivated and used with success in the destruction of the hypertrophied tissue. I doubt, however, whether this natural instrument is as successful as the manufactured curette or forceps, especially if the growths have assumed a fibroid character.

The method employed is immaterial so long as the tonsil is completely extirpated. A small portion of lymphoid tissue remaining may give rise to further difficulties. If we follow the custom of regularly examining the adjacent parts

of patients complaining of aural symptoms, we would frequently discover the origin of their discomfort.

In closing I can not offer a more appropriate thought than the one expressed in the words of Hamlet :

That we find out the cause of this effect ;  
Or rather say, the cause of this defect,  
For this effect defective comes by cause.

---

#### DISCUSSION.

Dr. T. V. FITZPATRICK, Cincinnati, Ohio. I most heartily concur in the doctrine set forth in this paper of the necessity of surgical interference in cases of adenoid vegetations or hypertrophy of Luschka's tonsil. Since the paper of Meyer, of Copenhagen, of twenty years ago, but little new has been said in favor of the necessity of surgical treatment of this hypertrophy. The evidence is only accumulative. What we need most is investigation of the cause or causes of this hypertrophy. My own observations are leading me year after year gradually to the conclusion that a state of suppuration, nasal or pharyngeal, is an essential precedent to the hypertrophy. I think we find a very apt analogy in the hypertrophied lymphatic glands in their attempt to carry off suppurative processes. Most of these cases will improve under antiseptic treatment, though I doubt if the true hypertrophy of Luschka's tonsil is ever cured by any antiseptic treatment, certainly not under many years. Suppurative rhinitis and pharyngitis in children is very common. Its far-reaching influence is probably due to the absorption of ptomaines. Recent investigations have shown in ozena that when a suppurative process is stopped the anæmia so often associated with it is arrested. We often find cases of adenoid vegetations of the vault of the pharynx anæmic. This can scarcely be due alone to the obstruction offered respiration by the hypertrophy, but is probably due to suppurative process associated with the disease. The theory of Hill, that this enlargement is due to the arrest of the migration of leucocytes, merits investigation. So far but little light has been thrown upon the cause, consequently nothing is done in the way of prevention.

To refer again to the disastrous influence which these lymphoid growths may and do exercise upon the organ of hearing, I can not too strongly advocate the course recommended by the essayist. He is right when he says that in purulent processes of the middle ear the routine treatment is entirely too often carried out, when an examination of the post-nasal space would readily reveal the cause of the recurrent attacks of suppurative inflammations. We must not always expect to find all the typical symptoms of adenoids presented in such children, but we must look for their presence in all cases where recurrent attacks of suppuration take place in young persons. I wish to also emphasize the fact that it has been my experience to find otherwise intractable cases of acute as well as chronic middle-ear catarrh frequently associated with adenoid hypertrophies ; and we would probably oftener see speedy and more permanent improvement in such cases if we would establish the rule to always examine the post-nasal space.

#### CRANIOMETRIC MEASUREMENT OF 500 SKULLS IN RELATION TO AURAL TOPOGRAPHICAL ANATOMY.

By B. ALEXANDER RANDALL, A. M., M. D.,

*Professor of Otology in the University of Pennsylvania and the Philadelphia Polyclinic.*

Aural anatomy and topography have of late years been the subjects of a number of interesting and valuable studies, stimulated by the increased specialization of otological work and the greater employment of bolder surgical procedures. The

question of the topography of the temporal bone has grown steadily more pressing, for the success attained by surgery in many directions is widening the operative field and urging the surgeon to intervene radically upon less vital indications than were formerly regarded as his sole justification. Especially is this the case in relation to mastoid trephining, which was reintroduced after a century of discredit, as a life-saving operation in cases of empyæma or caries of the mastoid. Now it is coming into use in the group of cases where intractability alone marks the case as dangerous, since the danger to life of skillful operation has come to be smaller than that of timid temporizing. Everything that tends to further lessen this peril constitutes a real step in the advance of otology in this and other directions, and gives promise of making it one of the most successful fields of medical practice, instead of being one that is now often, however unjustly, adversely criticised. Notable among these anatomical studies are those of Bezold, Hartmann, Zuckerkandl, Ruedinger, and Leidy, and from each of these we can claim important teachings, the two first having dealt specially with the operative aspect of the mastoid process. Bezold was the first to note a relation of aural topography to the form of the skull, and he pointed out that the lateral sinus was apt to be more forward and superficial, more vulnerable in ordinary mastoid trephining, in the short, broad head. He also laid stress upon the larger size of one lateral sinus, usually the right, because the longitudinal sinus usually passes almost directly into it, while the other receives only the smaller venous trunks. Without giving the statistics for its verification, he estimated that the right sinus is the larger in 70 per cent of instances, although in his 48 pairs of temporal bones there cited the left was larger 9 times and the right but 13. Schültzke gives 40 per cent as his finding in this respect, and among my 50 pairs the right sulcus is larger in 56 per cent. With this larger size there is often a more curved course of the sinus, which hollows a deeper channel forward and outward; and Zuckerkandl called attention to the occurrence of bulbous enlargements upon the vessel, which at times greatly increase its dangerous relations.

O. Koerner, of Frankfort, in an article in *The Archives of Otology* in 1887 (Vol. XVI, p. 281), expanded this view as to the influence of skull form upon the topography of the temporal bone, finding in his measurement of 60 skulls of various types and races that the brachycephalic crania, those short for their breadth, were distinctly the more dangerous. Hence, the mere measurement of the length and breadth of a patient's head would give strong presumptive evidence of the location of the lateral sinus and the middle cerebral fossa and have important bearing upon the question of the indications and prognosis of operation. So simple a solution of a difficult problem challenged attention and called for the further investigation of the matter, which Koerner invited. Many accepted the clear and plausible showing of his study as conclusive, while others, confirming his results in their earlier measurements, as I did, made clinical application of his rule with apparent satisfaction. Politzer, in his text-book, referred to the rule as likely to be valuable if confirmed by adequate statistics, but regarded 60 measurements as wholly insufficient. Schültzke, in the *Archiv fuer Ohrenheilkunde*, Vol. XXIX, p. 201, set forth a contrary series of results as his finding in a similar series of 60 skulls, pointed out some fallacies in Koerner's work, and left the problem as complicated as before. Koerner gave his measurements of 27 more crania as confirming his former results, and has since sectioned and remeasured some of the temporal bones previously measured to confirm his results. My studies were begun in 1888; but as I desired a wide basis before attempting any generalization, only a preliminary statement of my methods has been thus far published, and I much regret that I can now bring forward the figures of but one-half of the intended thousand.

Craniometry has by no means a settled and fully accepted method of determining even the fundamental points of skull dimension, and some of the discrepancies

between various workers lie in the matter of the primary conception of "skull index." Following some of the older craniologists, Koerner adopted the parietal protuberances as the points at which the skull breadth is to be measured, thereby obtaining figures generally smaller than the maximum breadth of the cranium and having no definite relation to it. Schültzke has followed the more authoritative method of obtaining the very greatest interparietal width, just as he takes the maximum length, from the glabella rather than the nasion to the occiput at its most prominent point, whether this be the inion or not. A greater breadth can at times be found between points on the squamæ of the temporals, but this may be from the springing of these bones out of place in the process of maceration. This is the method which I have followed, waiving any theoretical advantage which might be gained by measuring in fixed planes precisely at right angles to each other to obtain the length, breadth, and height. The index given is this maximum length divided by the maximum breadth, not the less convenient figures used by Koerner, who divided the breadth into the length. In the classification of the specimens, instead of assuming a geometrical line at the index 1.30, as does Koerner, as separating the long from the short crania, I have followed the best authorities in considering all skulls with indexes from 0.777 to 0.799, inclusive, as mesocephalic and constituting an intermediary type. This makes no little difference in the rating of crania. Thus one of the rare skulls having the transverse breadth at the parietal protuberances equal to the maximum, 134 mm., and a length of 172 mm., would be brachycephalic (with index 1.28) according to Koerner, while rightly rated as mesocephalic (index 0.779) in my tables. Another, 154:192, would hardly be brachycephalic (index 0.802), although markedly so (index 1.19) in Koerner's notation.

Yet further, in the more common instances where the width at the protuberances falls below the true breadth, the rating differs still more widely; and a skull 150:183, instead of receiving its true brachycephalic index of 0.814, would be held by Koerner to be dolichocephalic with index 1.32, because the distance between the tuberosities was only 138 mm. Besides these distinct differences in viewing the figures obtained, Koerner used a method of orthographic projection, rather than direct mensuration, to obtain the height of the floor of the middle cerebral fossa—a method possibly more exact for measuring the minimum distance, but only so after the point of greatest vulnerability has been otherwise determined. It must be admitted that the mensuration by calipers is almost sure to exaggerate the distances under the circumstances here met, since it is difficult or impossible to avoid slight obliquity in the position of their points. Yet this was fairly constant throughout the similar measurements of the investigation and usually too minute to be worthy of more than this passing mention. Accuracy to a fraction of a millimetre has not been attempted here; yet comparison with previous very careful measurements of the same crania has shown few and minute discrepancies, and only a very narrow margin of error can be conceded.

In deciding as to the dangerous relations of the sulcus of the lateral sinus, Koerner lays stress almost solely upon the superficial position, holding its forward position to be closely commensurate with its proximity to the mastoid convexity. No statistics are given in support of this view which had been set forth by Bezold and Hartmann; and he does not, like the latter, state the position of this thinnest point back of the meatus. Hence he leaves us wholly uninformed whether the temporal bones with the most superficially placed sigmoid sulcus, may not have been absolutely safe, since this portion of the sinus lay far posterior to the field of mastoid operation.

The orthographic method can be employed only on skulls sagittally or otherwise sectioned, a limitation which Koerner has himself felt; whereas far larger series of cranial measurements must be secured before any claim to rules of general

FIG. 1.—INSTRUMENT TO MEASURE WIDTH BETWEEN SIGMOID SINUSES.

FIG. 2.—DETERMINATION OF THE MOST VULN

ABLE POINT OF THE MIDDLE CEREBRAL FOSSA.

applicability can be ventured. A method has, therefore, been devised which can be used with any intact skull, is ready of employment, and yet gives results which are sufficiently accurate for all surgical purposes, for when it becomes a question of a fraction of a millimeter operative skill, rather than anatomical knowledge, must be relied upon to prevent disaster.

My procedure in measuring was as follows: With an ordinary pair of calipers the cranial length was taken from the most prominent part of the glabella between the superciliary ridges to the most distant point of the occiput, often above the protuberance. This length was then read off by applying the points to an accurate millimeter scale. The extreme breadth was similarly taken between the parietals, with the calipers held exactly transverse and their points on the same level. The distance between the parietal protuberances was also taken as by Koerner. In like manner was taken the width between the spinæ supra meatum and the intermastoid distance at an "operation point" 5 mm. behind the spina with the ordinary calipers, or the sliding calipers described later. For the maximum width between the sigmoid sinuses a special instrument was employed through the foramen magnum, a pair of inside calipers as figured in the cut. (Fig. I.) A plain pair of calipers then served to measure the thickness of bone between the sulcus and the operation point, 5 mm. back of the spina, between the sulcus and the back wall of the auditory meatus, and at the thinnest point of the mastoid, where the sinus most nearly approached the surface of the process. The distance of this thin point posterior to the spina was also noted. To determine the position of the most vulnerable part of the middle cerebral fossa, a sliding caliper (Fig. II), like a shoemaker's measure, was used to take the position and plane of the spinæ, and a detached L scale, as figured (b), was passed through the foramen magnum and applied to the lowest and most external part of the fossa, as determined by sight aided by touch. Its external portion was then brought into relation with the outside calipers, its rectilinear position secured by application of its mortised block to the lower edge, its relation to the plane of the spinæ secured by apposition of the surfaces (or any deviation from that plane made evident), and then the position of the point read off as to its height and lateral distance within or beyond the spina. The figure makes clear the manœuvre, which was really simpler than the description may suggest. The relative size of the lateral sulcus of each side was then determined by the eye and similarly that of the jugular caput and foramen. All the more difficult measurements were made in strong light, generally full sunshine; and the translucency of the bone permitted much more to be seen through the foramen magnum than might be expected, while it made easy the location of the most superficial portion of the sulcus, and in the dangerous bones made the condition readily manifest.

The crania measured consisted of the Hyrtl and other collections in the Mütter Museum of the College of Physicians of Philadelphia, the skulls in the Wistar and Horner Museum of the University of Pennsylvania, about 100 specimens in the Army Medical Museum in Washington, and lastly a number in the Academy of Natural Sciences in Philadelphia. To the curators of these museums and to others who have kindly aided me in my researches, I desire here to tender my grateful acknowledgment. The specimens utilized were unselected in so far that I have presented here the figures of every measurement completed. Adult Caucasian crania were preferred when they were at hand; deformed specimens were excluded, and a number of partially measured crania have been omitted from this report because of the incompleteness of the data. At the last, as the 500 was nearly complete, extreme specimens were sought in the rich collection of the Academy of Natural Sciences, in order to fill out symmetrically the groups into which I divided the various types. But no single specimen was introduced or omitted because of any selecting of specimens to point for or against any hypothesis.

In the detailed tables the figures are given for each cranium, and the width at the parietal tuberosities is given for the use of anyone who regards that as the proper position for determining the transverse diameter. Any other employment which can be made of the studies and any other conclusions which can be elicited from them will, I hope, be freely made. In the other tables I have summarized the findings which appear to me to be their most important teachings.

TABLE I.

<sup>1</sup> Larger.<sup>2</sup> Equal.

Summarizing the results gained from these 500 skulls, we find that they furnish us with 80 crania of medium index (0.777 to 0.799) and 210 on each side of this mean, not a few of which are extreme examples of the long and short head, respectively. Tabulating the figures, it is at once manifest that while Koerner's claim is perhaps sustained, that the right sigmoid sulcus more closely approaches the mastoid surface than the left, and is more superficial in the brachycephalic skull; this difference averages but a fraction of a millimeter; and the thin point is a little nearer the field of operation in the dolichocephalic. More important in this connection is the occurrence of minimum results in crania of every type and on either side—the left sulcus being the larger or the more superficial in 25 to 30 per cent. Yet the value of Koerner's measurements, when confirmed, is greatly lessened when we note that the approach of the sinus to the surface is not accompanied by a commensurate forward position; for the distance of the sulcus from the back wall of the external auditory meatus averages some 6 mm. more than from the mastoid surface, and holds no constant relation to the other dimension. It is, perhaps, smaller in the dolichocephalic; although in both types rather smaller on the right side.

Still more practical seem the figures indicating the "operation room," that is, the space intervening between the lateral sinus and the chisel of the operator when he begins to trephine the bone at a point but 5 mm. back of the spina supra meatum. This appears to average nearly the same on the two sides, although more often less on the right; but it is a millimeter smaller in the long head than in the short head, and is sometimes only 1 mm. or less, so that careful inspection would probably detect the dark sinus close beneath the bared surface. Zuckorkandl has described a temporal bone in the Vienna collection which presented a large dehiscence of the mastoid convexity, where the sinus wall was exposed; and this study cites a specimen in the museum of the Philadelphia College of Physicians, a Tartar adult male, of 0.68 index, where there were 2 mm. of bone covering the sinus externally, but a large dehiscence into the upper back wall of the meatus. No craniometric finding, therefore, can in any way relieve the surgeon from the apprehension that, in the case before him, the lateral sinus may be so superficial and anterior as to preclude operation in the usual way. No plan of operation and no instrument will insure safety; and Hartmann's rule is fully justified, always to operate as though the position of the sinus were probably a very dangerous one. This becomes the more clear by study of the second table, where the general averages of all the 500 skulls are presented in contrast to those of the 60 crania at each end of the series, which constitute the extreme examples of the opposed skull forms. Here appears the curious contradiction to Koerner's hypothesis in that the extreme brachycephalic skulls presented on the right side no instance of minimum results, gave on the average more operation room than the dolichocephalic and presented a larger right sulcus and a dangerous relation less often than the general average and still less often than the opposite long type of head.

Turning now to the second point of danger to be avoided by the operator, the relation of the middle cerebral fossa to the operation field, we find another diametrically opposite result from Koerner, in that a precarious position was more common on the left side than on the right in every type of cranium, and in the dolichocephalic rather than the brachycephalic, thus confirming the finding of Schülzke. The extreme types of skull are seen to be closer to each other than to the general average in this regard, each showing nearly the maximum height at times, or again a fossa reaching exactly to the level of the upper margin of the external meatus. In no instance was the middle cerebral fossa found lower than this fairly convenient landmark, and in almost all instances the floor was higher in the operation field farther back; so that a trephining channel which did not go above this level would seem always sure to avoid all danger. This may be considered sufficiently accurate for all practical purposes. Where we come to fractions of a millimeter in dimensions, safety becomes a question of surgical skill, not of anatomical knowledge.

Some description of the instruments devised and their methods of employment should accompany the diagrams and make clearer the measurements taken. The inside calipers (Fig. 1) consist of a crossing pair of slightly curved arms 120 mm. long, pivoted 75 mm. apart, and centrally slotted through about half their length in order to articulate with a graduated rod sliding in a vertical mortise through the center of the base. Movement of this vertical rod forward or backward symmetrically separates or approximates the tips of the calipers, and their distance apart at any moment is accurately shown by the graduation upon the scale. The points can be brought close together for easy introduction through the foramen magnum, there expanded until they meet the sides of the sulcus on each side, their most external position found and verified by observation through the same opening, and then the distance read off to a fraction of a millimeter. The plane of this measurement is easily determined in relation to that of the spinæ, the outside calipers serving, at need, to demonstrate its exact distance back, and any lack of symmetry in the height or distance out or behind the spinæ.

The instrument for measuring the relations of the middle cerebral fossa consists of a sliding caliper scale (*a*), with curved points, of sufficient length to embrace the skull from below and close upon the "spina supra meatum" or the depressions just behind them, where they are readily held by light pressure. The second part of the instrument (*b*) consists of an L scale with an arm 50 mm. in length and a mortised block sliding upon it so as to furnish an edge at right angles to its length. Introduced through the foramen magnum, the tip of its curved arm easily finds the lowest and most external portion of the middle cerebral fossa or any other point more exposed to injury by proximity to the trephining track, the surface of its long arm is brought into apposition with the external scale, so as to show that the tip is in the plane of the spinæ, its sliding block is pressed against the lower edge of the external scale to secure its vertical position, and then the height of its tip above the spina can be read off from the graduation. At the same time, its outer edge, which is just 50 mm. internal to the tip, indicates upon the outside scale by what amount the measured point lies within or beyond the spina,—e. g., in the figure it marks 53 less  $50 = 3$  mm. within. As the fossa often overhangs the spina, the reading may be negative by as much as the scale shows less than 50 mm. The same measurements may then be made upon the other side, without shifting the outside scale, by taking the difference between the two readings on the horizontal scale and subtracting 50 mm. The sliding caliper is made of such size as to serve for taking all the external dimensions of the skull; but these were quite generally taken with an ordinary pair of calipers, graduated in millimeters. The same were employed, with one branch introduced through the foramen magnum, to measure the distance between the sulcus and the mastoid surface or the back wall of the meatus—the latter measurement being rarely possible in a horizontal plane, as the instrument had to be so inclined that the plane of its tips sloped up and forward about  $30^\circ$ . Similarly the thickness of the bone between the sulcus and the exterior of the mastoid was slightly overestimated through measuring in a somewhat inclined plane. The small errors thus introduced were inconsiderable and fairly constant throughout the series.

In the detailed tabulation following, the crania are designated for purposes of identification by their museum numbers. In (C) College of Physicians, Philadelphia; (N) Academy of Natural Sciences, Philadelphia; (U) University of Pennsylvania; (A) United States Army and Medical Museum, Washington; and (P) private collections. The age, race, etc., are given as far as known, in the column of remarks.

## ADDRESS BY THE PRESIDENT OF THE SECTION, DR. A. H. OHMANN-DUMESNIL.

## AMERICAN DERMATOLOGY.

GENTLEMEN: I have the honor, not to mention the pleasure, of bidding you welcome to the deliberations of the section on dermatology and syphilography of the Pan-American Medical Congress. We are assembled here as representatives of American dermatology and we will be judged by our works. It may perhaps seem strange that I speak of American dermatology. Yet the day has come when we are to be emancipated from the thralldom of the Old World, which has for so long bound us in its fetters. It is within the memory of almost everyone present when if any fact or observation did not emanate from Europe it was treated as either worthless or not deserving of attention. The Western Hemisphere was dependent upon the suffrage of Europe, and as a result nothing but European ideas dominated us. It took many years of earnest work and independent thought to establish the position which is slowly gaining ascendancy among us and which destiny has decreed shall place us in the front rank of investigators.

In following the rise and development of American dermatology it will be noted that no inconsiderable weight was exercised by the French school at its beginning. Ricord in syphilis, aided by the French dermatologists, found many enthusiastic and apt pupils who returned to this country full of the precepts and enthusiasm of their teachers. There seemed to be little liking and still less demand for anything which did not emanate from Paris. In fact, the capital of France at that time was the center of arts and sciences of the civilized world, and what was beyond was "*οἱ βάρβαροι*" of the Greeks. And the sway thus established did not last for a few years only, but exercises its influence to this day. For, although this country has been emancipated from the yoke, to assume another one for a space of time, if I mistake not, the Latin-American countries of this hemisphere still acknowledge the supremacy of the French school.

Following this came a marked revulsion in feeling, due to the influence of Hebra and the Vienna school. Every one flocked to the school of the celebrated Austrian teacher and sat at his feet to absorb his precepts and teachings. He had the art of demonstration which carried conviction to the minds of his hearers, and he has to-day, perhaps, more disciples than any other dermatologist could ever count among his followers. In fact, he founded a school, that of Vienna, which, in spite of all the advances made, still makes struggles, far from unsuccessful, to maintain the supremacy which lay in its hands for so long a time. Its influence may be felt to-day all over the world; and, whilst it could not endure for all time, the master mind which guided it will be felt for many years to come. The acquired facts of dermatology and the practical applications to be derived therefrom were directed into new channels, which immediately became productive of new ideas and of principles of the highest value. The impetus thus given has not ceased to be fruitful and productive. On every hand we encounter pupils of the great master and reformer, and they number among the best and most prominent dermatologists of our country. In almost every work we take up we can detect evidences of the influence of the Vienna school, and it must be said in justice to it that, through this very influence, order has come out of chaos, and dermatology has assumed its proper place in the art of medicine.

Another factor which has had more than an ordinary influence on American dermatology is that due to the impetus which has been exercised by the English. Although conservative, to a fault almost, everything they have done has been executed with a conscientiousness that bordered upon the hypersensitive, and as a result we find to-day a large number of practitioners who depend wholly upon

Erasmus Wilson. This author did more, perhaps, than any other who wrote upon skin diseases to popularize the study of these affections among the English-reading portion of our medical population, and it is due to him to state that he was the pioneer who made the road easier for subsequent British writers on the same subjects, and their latter-day successes owe much of their popularity to the indefatigable worker of more than a quarter century ago.

The American is known to be the result of a combination and fusion of different peoples, and as a rule the best of the qualities of these have been retained in the product resulting therefrom. This being the case, there is no cause for surprise at the resultant being a race which is quick, perceptive, and ingenious, not to mention its inventive faculties. In addition to this, a certain independence in spirit and in lines of thought has had a far-reaching influence in bringing the American nation to the position which it occupies to-day. These qualities have been among the prime factors which have placed American dermatology on the plane which it occupies to-day.

For a long time original investigation, and in consequence original ideas, had no opportunities in which to develop. Everyone almost seemed to be satisfied with the *obiter dicta* which were sententiously announced *ex cathedra*. But that spirit of restlessness and inquiry which are the necessary accompaniments of enlarged views and higher education led to investigation, and the result is plainly indicated in the achievements which daily adorn the pages of current medical literature and which are reproduced the world over.

American dermatology has established a position for itself which, in view of the various disadvantages which it has had to overcome, as well as the preconceived ideas which had to be and still must be combated, it can well be proud of, especially when we take into consideration its achievements and the great promises for the future which it holds forth. No "pent-up Utica" is sufficient to set bounds for it. The men who are now prominent in the field are all hard workers, whose interest in their chosen study did not originate yesterday, nor will it cease to-morrow. It is ever-present and always progressive. It is destined to be more and more fruitful, and its promises for the future are most glowing. A characteristic of American dermatology, as it is of all branches of the medical art in this country, is that much more attention is paid to the clinical and therapeutical phases of a subject than to the purely pathological. Of course this does not signify that pathology has been ignored by any means, but not so much attention has been paid to it as on the Continent. Despite this, we have contributed some of the most valuable articles on diseases of the skin, in every particular, that have been included in accepted dermatological literature.

The independence of thought and originality of investigation spoken of before have had no small influence in the work of laying the foundation for what promises to be a noteworthy structure, which is destined to attract the attention of the world. I refer to a distinctively American school of dermatology. Our therapeutic methods have a tendency to simplicity, and in general we trust more to personal investigation and verification. There is a much greater impulse to determine the true etiological factors of disease, and as a result greater independence in the application of therapeutic methods. The formal utterances of authorities have but little weight with the rank and file, whose experiences in many instances have entirely changed preconceived opinions which were based upon insufficient data.

Taking all these facts into consideration, there can be no doubt that progress of a marked and practical character is taking place in America, and a large increment to the total will be the inevitable result of a gathering such as the present one.

We, and the rest of the world with us, are ignorant of the wealth of material which lies "unknown, unhonored, and unsung" in the vast recesses of the West

Indies, Sandwich Islands, and South American States, not to say Mexico and Central America. Give us all this wealth of material, for which we will gladly exchange that which lies in our hands, and the day will not be far distant when the Western Hemisphere will be enabled to boast of an American dermatology which will have arisen to the dignity of a school second to none and respected above all.

This is our beginning; and the fervent prayer of him upon whom the high honor has devolved of presiding over your deliberations is, that it will prove the end of the entering wedge which will lead to those results which the ability and progressive spirit and energy of all Americans are competent to accomplish.

## PAPERS READ BEFORE THE SECTION.

---

### THE MILIARIA GROUP.

By S. POLLITZER, A. M., M. D., of New York.

Besnier and Doyon,\* in a note to their translation of Kaposi's treatise, remark that our knowledge of the sweat glands, as compared for instance with that of the sebaceous glands, is very deficient. It is not difficult to account for this fact when we consider the obstacles which the location of the chief portion of the gland, deep in the cutis, creates; that the great number and close relations of the glands make it impossible to observe clinically the beginning of a disorder in a single gland; and, finally, that the early involvement of the neighboring cutis in most cases entirely obscures the relation of the sweat gland to the pathological process. There is no reason, however, to believe that the sweat glands are favored with any special immunity from the disorders to which all glandular structures are subject. It is nearly thirty years since Hebra† wrote that up to that time no diseases of the sweat glands involving structural changes had been described, and since that time not much has been added to our knowledge. The host of young dermatologists, however, in the great medical centers, who are subjecting all the diseases of the skin, the common not less than the rare, to a rigorous microscopical study, and the improved methods of examination augur well for our progress in this special department, not less than in the whole field of dermatology.

To review for a moment the organic diseases of the sweat glands, which have already been described, it was my good fortune to be the first to establish as a disease of the sweat glands,‡ on the sure footing of pathological anatomy, a disorder which the keen eye of the great French clinician Verneuil had led him to locate in the sweat glands, and which he called, on purely clinical grounds, "hidrosadénite phlegmoneuse," and the papers of Dubreuilh have corroborated my results. At the present time there exists some confusion as to the pathological relations of adenoma of the sweat glands. Darier and Jacquet's "hydradénomes éruptifs" and "adénomes sudoripares," Török's "syringo cystadenoma," Perry's "adenoma of the sweat glands," Quinquand's "cellulome épithélial éruptif kystique," etc., describe conditions which have been referred to the sweat glands, but many of them, we know now, are independent of these structures; in fact, with the exception of two or three cases in which a true adenomatous proliferation was found disguised under other clinical conditions,§ no case of this

§ Elliot, Jour. Cut. and Gen. Dis., May, 1893.

form of tumor has been described. These benign epithelial growths of the skin are being now vigorously studied, and we may soon hope for fuller light on the subject.

It appears certain that malignant (cancerous) growths may originate in the sweat glands, and when we have added atrophy, hypertrophy, and fatty degeneration of these structures we have almost exhausted the brief register of the organic diseases of the sweat glands. There remains only the group which forms the subject of this paper.

I propose to group together three disorders of the sweat gland apparatus which depend on an obstruction to the flow of sweat through the duct. The term *miliaria* is now used to designate an eruption of minute vesicles or papules with clear or cloudy contents, associated with excessive sweating; and the various terms *sudamina*, *M. crystallina*, *rubra*, *alba*, *vesiculosa*, *papulosa*, and *lichen tropicus* have been applied to two distinct disorders, sometimes indiscriminately.

*Miliaria crystallina* or *sudamina* consists of an eruption of perfectly clear transparent vesicles from the size of a pin's head to that of a split pea, that develop anywhere on the body in the course of some general febrile disease (articular rheumatism, puerperal fever, typhoid, etc.). They have been aptly described as resembling drops of dew scattered over the surface. They are accompanied by no subjective symptoms whatever, are of brief duration, and their disappearance is followed by but slight desquamation. The eruption is entirely without diagnostic or prognostic value to the disease with which it is associated.

The anatomy of the vesicle has been studied by Haight, Robinson, and Török. They agree that the vesicle is located wholly in the horny layer of the epidermis, and that a sweat gland duct may generally be demonstrated leading into it. The vesicle depends on an obstruction to the outflow of sweat, which, unable to escape, distends the tissues below the point of obstruction. This obstruction must be located in the uppermost layers of the stratum corneum, if not in the very surface of the integument. Haight's theory of the cause of the development of this vesicle was, that in a sudden outflow of sweat the current forces one turn of the spiral duct against another, forming a valvular occlusion. This view, it seems to me, is not tenable. Such an occlusion would naturally take place at the first spiral turn in the course of the sweat current and not at the last. The vesicle would therefore be located at the bottom of the rete and not at the top of the horny layer. A more reasonable explanation, it appears to me, is that in the neglect to which the skin is necessarily subjected during the anhydrotic stage of the fever in connection with which the rash occurs, the orifices of the sweat ducts become blocked up by epidermic debris, and nutrition changes in the epidermis, due to fever, may aid in producing this effect. The fluid, when the perspiration is restored in the "critical sweat," can not pass the obstruction in the surface and distends the tissues just below the point of occlusion.

In *miliaria rubra*, called also *lichen tropicus*, *miliaria vesiculosa*, *miliaria papulosa*, *miliaria alba*, *eczema sudamen*, and prickly heat, the seat of the lesion is somewhat deeper. The affection is too well known to require more than a few words as to its clinical appearance. It consists of minute vesicles or papules on a slightly reddened skin, which itches and prickles intensely. The contents of the older vesicles are sometimes cloudy or opaque, and they have a whitish appearance; hence the term *M. alba*. Aside from the evidence afforded by the histological examination, the clinical appearances and the course of the disease alone negative the view of the Vienna school that *M. rubra* is an *eczema*. No *eczema* will remain for weeks in the erythematous-vesicular stage without weeping, and no *eczema* will disappear, as does prickly heat, sometimes within twenty-four hours, leaving hardly a trace. I have before me many gentlemen who come from tropical countries, and who have large experience with prickly heat. It can not be necessary to dwell on the manifest differences between an *eczema* and this disease.

The anatomy of miliaria rubra has been studied by Robinson, Török, and myself. Robinson regards the affection as an eczema. Török looks upon it as due to sweating, but the vesicles are not, according to him, associated with the sweat ducts. My own observations published in the Journal of Cutaneous and Genito-Urinary Diseases, February, 1893, were based on the histological study of eight cases in different stages and from patients ranging in age from the infant to the adult. I reported in that paper that I had found the vesicles to be always connected with the sweat ducts, but subsequent studies on other cases lead me to modify this statement somewhat. I agree with Török that the vesicles are sometimes the result of inflammatory colliquative changes in the epidermis, but believe this form of vesicle to be the exception and to occur only in cases attended with a great deal of irritation. The characteristic vesicles are always found in or below the stratum granulosum, but the entire sweat canal in the epidermis is distended often with fluid below this point, forming a funnel-shaped spiral canal.

Serial sections are necessary in many cases to enable the observer to determine with certainty the relation of the sweat gland to the vesicle. The contents of the vesicles—which it would be correct in some respects to call cysts—are at first perfectly clear; later they become filled with cellular elements and the spaces are sometimes occupied by a compact mass of granular elements and epithelial detritus. It is in this stage that they clinically resemble papules, though a minute vesicle deep in the epidermis will also give the appearance of a papule. Otherwise the only histological appearance to account for the clinical picture of the minute papules which have given the name of miliaria papulosa or lichen tropicus to the affection consists in a minute circumscribed thickening of the horny layer at the orifice of the sweat duct. There is in the cutis only a slight amount of perivascular infiltration, but here and there the emigration of white blood corpuscles in the papillary layer is very considerable, and it is above such patches that vesicles of colliquative origin sometimes appear. This evidence of inflammation is only natural when we consider the great strain on the papillary blood vessels and the vasomotor nerves due to the heat and the added effect of the irritation from the blocked-up sweat ducts. We have no positive data for an explanation of the blocking up of the ducts while the sweating is so active as in those who acquire prickly heat. In my publication\* on this disease I have advanced a theory to account for this phenomenon. The horny layer, bathed constantly in sweat, becomes saturated with watery fluid, and the cells, swelling by imbibition, occupy more space vertically and laterally and thus spread over the orifices of the sweat ducts, occluding them at a moment when the flow of sweat is temporarily in abeyance. The next flow of sweat meets the obstruction in the horny layer and, unable to escape, distends the epidermis first of all just below the point of obstruction; that is, below the lowest layers of the horny layer, and later, as the amount of secreted fluid increases, the distention involves the entire canal in the epidermis. That such a swelling of the cells of the horny layer actually occurs, I have demonstrated in the paper referred to. The saturation with fluid may be so great and so constant that the horny layer in the neighborhood of the sweat pore assumes something of the appearance of that of a mucous membrane; its nuclei are well preserved and take nuclear stains readily. We must still, however, account for the fact that although all persons sweat in hot weather, not everybody acquires prickly heat, or, to express it in the terms of my theory of the pathology of the disease, not every horny layer imbibes the water of the perspiration and swells. To explain this difference in the behavior of different horny layers under apparently similar conditions, I have taken into account a factor which we know differs in different individuals and in different parts of the skin in the same individual; that is, the different degrees to which the skin is normally supplied

---

\* *Loc cit.*

with fat. Horny cells impregnated with fat can not absorb water, and therefore will not swell up and occlude the sweat ducts. Natives of tropical countries have, we know, particularly well-oiled skins, and are for this reason but little subject to prickly heat, while the inhabitant of a temperate climate resident in the tropics, who, perhaps, like the Englishman in India, takes his daily bath or two, suffers intensely from this affection. No portion in the integument sweats more abundantly than the face, where prickly heat practically never occurs; the face is better supplied with fat than any other region. There is a therapeutic hint in this theory which I should like to suggest to some of my confrères from the South. It is to prevent the imbibition of water on the part of the horny layer before the disease develops in those who are subject to it by providing an abundant supply of fat by means of inunctions with some fatty body. Of course, after the disease has once developed, soothing applications, especially powders, are indicated.

Miliaria profunda is a disease which was first described by Robinson\* in 1884, and which until very recently remained without a name. It is true that Jackson,\* in 1887, described the disease under the name of "dysidrosis of the face," from a fancied resemblance to the disease of that name affecting the hands, described by Tilbury Fox and Hutchinson, but aside from the fact that the existence of Fox's dysidrosis as a disease of the sweat apparatus is still *sub-judice* the resemblance between our disease and Fox's is so remote that Jackson's name was generally received with great reserve. A case of the disease has been described by Rosenberg, of Berlin, and Hallopeau, of Paris. I have seen several cases, and Robinson, in a recent paper, says that he has seen perhaps forty cases in the last eight or nine years. The rash consists of nodules of a translucent boiled-sago-grain appearance, from the size of a pin's head to that of a pea, located in the face, especially around the nose, on the cheeks and forehead. It is most common in middle-aged women, though I have seen it in children and adolescents. The nodules undergo no change after they have once formed, as long as the weather remains warm, but on the approach of winter they slowly disappear, to recur again the following summer. If they be incised a drop of perfectly clear watery fluid escapes. They occasion no subjective symptoms whatever. The anatomy of the disease has been studied by Robinson and by myself. The conditions are very simple. There are no changes in the epidermis, except perhaps those due to pressure. The corium is occupied by a cyst of clear contents, whose walls consist of a double layer of epithelial cells on a basement membrane. The coil glands show no changes, except sometimes an increase in the width of their lumen. The condition is clearly one of cystic dilatation of the sweat duct, the dilatation occupying the corium, and the obstruction on which it depends must therefore lie below the epidermis. Given such an obstruction, the secreted sweat must distend the canal, through which it can not escape. With the approach of cold weather and the cessation of sweating the sweat in the cyst is absorbed and the lesion apparently disappears. On the reëstablishment of the sweating the following summer, the affected duct is again distended by the secreted fluid. Since the obstruction lies in the corium, it is not desquamated with the epidermis, and the condition is therefore permanent.

When this paper was planned the disease had received no name except that of "dysidrosis," a term to which there were manifest objections. In the last number of the Journal of Cutaneous and Genito-Urinary Diseases (August, 1893), Dr. Robinson has a paper on this disease, to which he now gives the name "hidrocystoma." The name is certainly appropriate in that it conveys a fair idea of the pathological condition. I see, however, no reason to modify my suggestion as to the name "miliaria profunda." The aim of this paper is to emphasize the fact that there is a group of diseases of the sweat glands which have as a common feature the occlusion of the duct of the gland without injury to the secreting coil.

---

\* Jour. Cut. and Genit. Dis.

There results, therefore, in all a kind of retentive cyst. In the first or superficial miliaria, *M. crystallina*, the obstruction is in the uppermost layer of the stratum corneum; in the second variety, *M. media* or *rubra*, the obstruction is in the lower horny layer, just above the level of the stratum granulosum; in the third, *M. profunda*, hidrocystoma, Robinson, the obstruction is entirely below the epidermis. To two of these conditions the name miliaria has already been given and is sanctioned by long usage. It seemed but natural, therefore, to apply this name to the third disease, and thus to include under a common name diseases which are pathologically and etiologically so closely related. There is, of course, a well-grounded objection to the multiplication of names in dermatology; but when its purpose and tendency are the simplification of our knowledge of a group of diseases it seems to me not only justifiable but a distinct advantage. On this point I should be glad to hear the views of the section.

---

#### DISCUSSION.

Dr. DUHRING. The diseases cited by the reader of the paper all belong to the same group, but in classifying them it is a question whether they should not be separated, for the reason that some are non-inflammatory and others are distinctly inflammatory. If a pathological classification be adopted, which seems best at present, they should be separated, miliaria rubra, or prickly heat, being placed with the inflammations. The anatomy of the several diseases of the sweat glands has been clearly set forth by the reader, thus elucidating the exact seat of the affections referred to.

Dr. RAVOGLI. I would not agree exactly with the author to call miliaria any disease of the sweat glands when we see miliaria where no symptoms of inflammation are present. For instance, I have seen frequently cases of typhoid fever showing eruption of miliaria crystallina on the abdomen and on the upper part of the thighs. In these cases the vesicles of miliaria looked just like drops of water sprinkled on the skin, and it was difficult to believe that the fluid was contained in the epidermis, so clear were they. This kind of miliaria scarcely can be said to depend on any trouble of the sweat glands, and so any inflammatory symptom shows affection of that glandular apparatus. In the cases of prickly heat there is a true inflammation of the meatus of the sweat glands, and this can be considered as a form of hidrosadenitis; the meatus of the glands is surrounded by a vesicle and appears red and inflamed. In the same way we have inflammation of the sweat glands in the depth of the corium and of the skin, producing hard and painful nodules under the skin. Rasori described one of his cases which occurred after the injection of one-fifth of a grain of pilocarpine, where the patient, after the profuse perspiration, showed nodules all over the body, which, examined under the microscope, showed to be inflamed sweat glands. I disagree with Dr. Pollitzer only on account of the name, highly appreciating his scientific remarks and observations of the facts.

Dr. POLLITZER, New York. I am very glad to hear Dr. Duhring express himself so strongly in favor of a classification based on pathology. I am surprised, therefore, that my classification of this group of diseases, based as it is strictly and solely on their pathology, does not meet with his approval. I believe that Dr. Duhring's objection is directed, not toward the real point of my contention that the three diseases which I have discussed belong together, but rather toward the name "miliaria," under which I have grouped them. This name, however, is not of my creation; it is already in common use for two of these affections, *M. crystallina* and *M. rubra*, and rather than invent a new name I have applied this term to the third member of the miliaria group. When Dr. Duhring objects to the term for

these three diseases on the ground that miliaria implies an inflammatory affection, he forgets that the name has been used for *M. crystallina*, a disease certainly not inflammatory. Surely Dr. Ravogli has misunderstood me. I should be the last person to confound hidrosadenitis and miliaria. Rasori's case, which was described at the London International Medical Congress, 1881, presented no features which require its mention in this connection. The only lesions present were small, deep nodules which were thought to be enlarged sweat glomeruli.

### RHINOPHYMA.

By WILLIAM S. GOTTHEIL. M. D., of New York City.

Rhinophyma in its advanced stages is not common in this country, and examples of it come but rarely to the notice of the dermatologist. It is essentially a European disease, being most prevalent in Germany, Hungary, France, etc., the so-called "wine countries." Here the use of water as a beverage is practically unknown, the light red and white wines forming the sole drink of the people. In the beer and liquor countries, such as England, North Germany, and Russia, the disease is much rarer. The cases seen in this country are usually in foreigners, their foundations being laid abroad and their bearers transplanting to and continuing in this country the habits of their native land. In the lands of its prevalence rhinophyma enjoys a multiplicity of names. The prominent and unconcealable deformity and the very general belief in its origin in wine-bibbing have led to a number of popular nicknames. The French call it "couperose," copperas, though it is more like the metal itself in color than the green salt. In Germany it is "kupfernase" (copper nose) and "pfundnase" (pound nose); appropriate designations both. Its delineation forms a staple subject for the caricaturist, and its place in comic opera is an assured one. Nevertheless, to the patient afflicted with rhinophyma the deformity is a very tangible and unmitigated misfortune. It must be presented to strangers with his name when he is introduced; he must carry it with him on the street and in his business; he must be the perpetual object of the commiseration, open or concealed, of his friends and relatives. Unmannered people jeer at him, and even those whom education should have taught better manners stop to take notice of and to marvel at his peculiar appearance. I have seen patients driven almost to desperation and on the verge of suicide on its account.

Gamberini calls rhinophyma an elephantiasis of the nose. The phrase is a correct enough one from a descriptive point of view, but is liable to lead to confusion with other elephantiasis, as that of the Arabs and that of the Greeks. The latter, of course, is an elephantiasis only by mistake; the Greek writers thus designate a malady that they knew by hearsay only. Its true name is "lepra" (leprosy). Elephantiasis arabum, on the other hand, is a pachydermia probably of parasitic origin. It rarely affects the upper extremity and never the face. The term "elephantiasis" should be reserved for it alone, or, better still, it should be dropped entirely from dermatological nomenclature. Rhinophyma is a chronic hypertrophy of the connective tissue of the cutis vera of the nose, the peri-nasal portions of the cheeks and forehead, and the lobes of the ears. All the vascular structures, the arteries, veins, and capillaries, are thickened, dilated, and increased in number. The glandular structures of the affected skin are enormously hypertrophied and pour a greatly increased amount of altered secretion. In a fully developed case the increase of all these three elements of the organ is well marked. The size of the hypertrophied organ varies greatly. It may be so slight as hardly to attract attention, and it may be so great as to interfere with deglutition and even with respiration, and to greatly discommode the patient by its weight. In a

well-developed case the nose is generally enlarged in three distinct portions or lobes, the central one representing the tip and the lateral ones the two alæ. All three may be symmetrically developed, or the central one may be far the largest and project well down over the lower lip. In some of the recorded cases the mass thus formed has been enormous; those that we see here are not permitted to become so large. The surface of the tumor may be smooth and rounded, but more often it is irregularly nodular and marked by deep depressions and furrows that partially subdivide it into a number of secondary lobules. Thus arise masses of the most varied and irregular shapes, long-pointed excrescences, pear-shaped pedunculated lobes, and broad flat tumors. The vascular dilatation and hypertrophy are largely capillary, and cause a diffuse discoloration that varies in hue from a reddish pink to a deep purple. The color depends on the comparative involvement of the arterial and the venous radicles, the former causing the brighter reddish and the latter the darker bluish tones. The organ will be either hot and sensitive to the touch, or cold and more or less anæsthetic. The larger blood vessels, whose multiplication in size and number form so prominent a feature in the early stages of the malady, are not noticeable, the inevitable contraction of the new-formed connective tissues having largely obliterated them.

The changes in the glandular structures of the affected skin are usually very marked, and are of the more importance in that they largely affect the prognosis as to the success of operative procedures for the cure of the deformity. In a certain number of cases the skin of the tumor is not apparently more oily than is natural; the mouths of the sebaceous glands are of the usual size, and suppurative glandular and periglandular processes do not occur. These cases, however, are the exceptions. Most often a thick oily secretion covers the nose or accumulates as seborrhœal scales upon the surface; the mouths of the ducts of the glands are wide and patulous, sometimes enormously so. I have seen them measure two lines and more in diameter. The abundant secretion of the hypertrophied glands dries up into hard, dark-colored plugs, forming prominent objects in the topography of the surface of the tumor. To this excessive development of the sebum-secreting organs is due the tubercles and pustules that almost always stud the surface of the rhinophyma tumors. The sebum at the mouth and in the neck of the excretory duct dries up and sticks fast; the accumulating secretion dilates the gland cavity and forms a retention cyst behind the plug, and the consequent irritation causes an inflammation of the gland and the surrounding connective tissue. The more of these suppurating glandular and periglandular structures there are, the better the chance for any fresh surface of the tumor to become infected with the streptococcus and the less chance there is for a good operative result. In the very latest stage of rhinophyma, a stage rarely reached in this country, the connective tissue new growth in its contracting gradually cuts off a part of the capillary circulation as well as the larger vessels. The nose then becomes paler and paler, until finally it may become snow white. Its temperature diminishes and its sebaceous secretion becomes less abundant, until it is even below the normal amount. The volume of the tumor diminishes as cicatricial contraction goes on, and thus to a certain extent the disease in its last stages works its own cure. This desirable result only occurs after the disease has existed a great number of years.

As regards the etiology of rhinophyma, it must be noted that whilst by some it is classified as a distinct disease, it is frequently the sequel to long-continued rosacea of the ordinary type. Most cases will give us the history of having long had red or livid, cold or hot, and oily noses, and in some the periodic occurrence of acne papules and pustules has been a marked symptom of the early stages. I was formerly of the opinion that it was simply the last stage of rosacea, a stage not reached at all in the vast majority of cases; but there are undoubtedly cases

in which there has been absolutely no antecedent rosacea; in which the enlargement has been the first symptom and long antedates the redness or the lividity. My own operative case, to be recounted later, was one of this kind. The hypertrophy was the first and for a time the only symptom. Again, rosacea is almost as common among women as amongst men, yet rhinophyma affects the male sex alone. So far as I know not a single case has been recorded in a female. It seems probable, then, that there are two distinct varieties of rhinophyma, undistinguishable by us as yet. One is the sequel to or the third stage of rosacea. Though extremely rare in comparison with the frequency of the latter disease, it includes by far the greatest number of the cases of rhinophyma that we meet with. The other is a connective tissue overgrowth from the beginning, to which the glandular and vascular phenomena are purely secondary. The causes of the first variety of the disease are of course those of rosacea, continued through long periods of time. We may leave out of account the rosacea of early womanhood aggravated at the menstrual epoch, and that not uncommon at the menopause, since women do not have rhinophyma. All observers agree that the habitual use of liquors containing alcohol is the active and efficient agent in the vast majority of cases. Perhaps we would be more exact if we ascribed it to the chronic gastritis, the anæmia, and the nervous debility that the use of alcohol induces. The various alcoholic beverages, however, vary greatly in their tendency to produce the disease in question. Beer is much less hurtful than wine and spirituous liquors, and some wines are worse than others in their effects. Hebra thought that the Austrian and the Rhenish wines, which are poor in alcohol, but contain tartaric acid and the ethereal oils in abundance, were more liable to produce it than the fiery and spirituous wines of Hungary and Spain. He claimed to be able to distinguish between the vivid red rhinophyma of the wine drinker, the cyanotic one of the indulger in beer, and the dark blue and smooth excrescence of the brandy drinker. Be that as it may, alcoholic excess and its consequences remain the chief efficient cause of the malady. But it is not the only one. Exposure to the weather, as in cab drivers and others, to heat, as in the case of cooks and firemen, must be credited with a certain number of cases. Even cold-water cures, too long continued, have been blamed for some cases. There remain others, however, and a considerable number of them, in which the etiology is absolutely in the obscure. No satisfactory cause for the hypertrophy can be found.

The pathology of the affection is not fully elucidated. All authorities agree in the presence of increased connective tissue in the corium, with dilated vessels and distended and hypertrophied sebaceous glands. Biesiadecki found a large increase in the number of blood vessels, both of the superficial layer and those going to the corium. Bulkley found in the softer parts of the tumor a more or less abundant cellular infiltration, the denser portions consisting of closely interwoven connective tissue fibers. The papillæ were gone, the stratum corneum was thinned, the arteries and the veins were enlarged and dilated. Contrary to all other observers, he found the sebaceous glands only moderately enlarged. Degenerative changes of the sebaceous glands and retention cysts from plugging of their ducts were found in most cases. Ohmann-Dumesnil, in a recent work on the subject, has laid especial stress on these latter. He found the cysts to be filled with cheesy fat and detritus, the specific characters of the sebaceous glands having almost entirely disappeared. He mentions one cyst of half an inch in diameter. The condition of the lymphatics has not been especially investigated. This is to be deplored, since the disease presents certain striking resemblances to elephantiasis Arabum or bucnemia tropica, a malady in which remarkable changes in these structures have been observed.

The diagnosis of this condition can present but little difficulty. It carries its name upon its face. Carcinoma and rhinoscleroma are the only two affections

which are liable to be mistaken for it, and in the former the ulceration and in the latter the characteristic microorganism should suffice to prevent all mistakes. The prognosis should be a guarded one. The remedy to be used is a varying one, but its successful application is often very difficult. Especially should we be cautious in promising results when the process is extensive, involving the skin at the root of the nose, the forehead, and the cheeks. Unless we have resort to very extensive rhinoplastic operations our work must be done almost entirely in diseased tissue and the result must be uncertain. It is to record and to emphasize these very points that the subjoined history of a case only partly successful is given.

Treatment is simple, and presents no points for divergence of opinion. Ablation, either simple or with the formation of a flap from adjacent parts to fill up the operative defect, is the only remedy. All other treatment, remedial or palliative, local or general, is entirely useless.

Theobald M., aged 60, Alsatian, resident thirty years in United States. July 2, 1892: Patient first noticed a swelling of the nose some two years ago. He is quite positive, and his assertion is borne out by his family, that there was no enlargement of the organ before that time and that he never had a red or inflamed nose in his life. A very gradual colorless enlargement began to be noticeable in 1890. The progressive increase continued in 1891, and the organ began to get red. Scabs began to appear on its surface and annoyed him very much. He is perpetually picking them off and irritating the skin. The increase in size and redness is still going on. There has been no medical treatment. The patient is a man of absolutely steady habits. He has never been a drinker, a single glass of ordinaire and water to his dinner being the only wine he consumes. He never drinks beer, and has not touched a drop of liquor for years. Being a shopkeeper, his occupation is an indoor one, and he is in no way exposed to the elements or to the heat of a fire.

*Status præsens.*—The patient is a perfectly healthy man and well preserved for his age. His internal organs are normal. His skin is coarse on face and neck. The entire nose is swollen and increased in size. Its color is a reddish purple, and the discoloration extends on to the central portion of the forehead, the adjacent parts of both cheeks, and the upper lip. The skin of all these parts is bulbous and ragged, but the main enlargement affects the tip and alæ of the nose. The mouths of the sebaceous glands are enormously dilated, forming great pits, some of which are as large as French peas. Large amounts of sebum can be expressed from the glands communicating with them, and the patient is in the habit of daily squeezing them out. The expressed material is whiter than the normal secretion of the glands, and apparently differs from it in constitution. When allowed to remain *in situ* in the dilated duct of the gland this sebum dries into the scabs that give him much annoyance. In spite of the general redness of the affected skin there are few visible vessels. A number of inflammatory papules and pustules are present, together with a great number of large black comedones. The columella is affected, but the interior of the nostrils is apparently perfectly healthy. An important point is that the lobes of both ears are enlarged and livid and evidently participate in the diseased condition. The nose measures  $5\frac{1}{2}$  inches around the projecting bulb. The overhanging mass interferes with respiration, especially when any catarrhal condition of the nasal mucous membrane is present. The tumor is greasy and cold to the touch. His psychic condition is a lamentable one. Residing and doing business in a far eastern district of the town, he is continually exposed to the remarks and the insults of those who see his deformity. He has the Gallic hastiness of temper, and though generally a mild-mannered man, has several times been in trouble on account of attacks that he has made upon persons whom he thought were ridiculing him. His family live in constant fear of an outbreak. For several months past he has not ventured out of the house, and he has made those around him miserable by his deepening despondency and constantly recurring threats of suicide. As I was on the point of going away for the summer when I first saw him, he was put upon indifferent treatment for several weeks. Among other things he took for some time large doses of arsenic. Of course it had no effect upon his disease.

On September 3 I operated upon him. The entire pendulous central lobe was ablated and removed down to the cartilages. The incision was a broad, elliptical one extending to the anterior margin of the alæ on both sides and to the middle third of the nasal bones and the columella above and below. Then the skin of

the alæ was dissected off in a moderately thin layer as far as the naso-buccal fold on either side, and the connective tissue removed almost to the cartilages below. The skin flaps were then carefully trimmed and the edges united in the middle line by 8 catgut sutures. As far as could be judged at the time the result was a good one. The entire central lobe had been removed; the very large and spreading alæ were greatly reduced in size; the line of incision was central, and the flaps were large and sufficient. The operation lasted some two hours, and its technique was beset with considerable difficulty. The hæmorrhage was enormous for so small an operation. The number of arteries to be twisted was very great, and many of them in the depths of the lateral flaps very hard to reach. It was impossible to prevent the blood running into the anterior nares and the mouth, and several times work had to be stopped to prevent the patient choking with blood. Two very small rolls of finger bandage were then placed on either side of the alæ to support the lax side flaps and the whole covered with a moist antiseptic dressing. On the third day discharge began to appear under the edge of the dressing, and it was removed. The state of things then found was not satisfactory. The flaps were swollen and every sebaceous gland in them was pouring out a purulent secretion. There was suppuration in the track of each suture, and the uppermost one had already come away. During the next three days all the other sutures ulcerated their way out, the entire wound opened up, and all hope of primary union of any part of the operative field was at an end. The attempt to obtain closure of the wound was most tedious and disappointing. It took from the 17th of September, 1892, to the 20th of March, 1893, some seven months, to accomplish it. The alar flaps preserved their vitality and healed up in two or three weeks; but the central pieces covering the dorsum of the nose simply melted away, leaving a defect three-fourths of an inch in breadth and  $1\frac{1}{2}$  inches long. At the bottom of this defect the exposed cartilages were for a long time visible. All attempts at granulation seemed to stop; the entire wound became glazed over, and the secretion from it almost ceased. It is needless for me to recount the many measures that I took in the long-continued attempt to stimulate the wound to granulate up. Months passed, and hardly any progress toward filling up was made. The sebaceous glands continued to pour out a puriform fluid; minute suppurative foci continually appeared, and more than once I was on the point of absolute discouragement. Finally, under such vigorous measures as thorough scraping twice a week with the sharp curette, followed by the application of pure carbolic acid and a creosote dressing, the wound finally healed.

The result, from a cosmetic point of view, has been only moderately successful. The projecting central lobe has indeed been removed, and the wide-spreading alæ have been much reduced in size. But a depressed scar one-fourth of an inch in breadth and more than an inch long occupies the dorsum of the nose. And, unfortunately, the malady of the skin that first caused the deformity has been progressive. The alæ have commenced to hypertrophy again, and the rhinophyma has increased on the cheeks, the root of the nose, and the lobes of the ears. At best the operation has been but a partial success, and that at the expense of many months of pain and effort. The effect upon the patient's morale has, however, been good. Relieved of the tumor that hung at the end of his nose his hypochondriasis has disappeared; he goes out among men again, and has regained his natural cheerfulness. Still, I should hesitate to claim that his appearance has been much improved by the operation.

I fail to find, either in the text-books or in the recorded accounts of such cases, any reference to any difficulties or sources of failure in these rhinophyma operations. In every case a simple statement that ablation or enucleation was done, or will suffice to cure the malady, is all that is said. Of course, the reason for my own partial failure is patent. I was dealing with and operating in diseased tissue. The flaps themselves necessarily contained foci of suppuration and pathogenic microorganisms. It was out of the question to attempt to remove all the diseased skin; to have done so would have been to remove the integument of the entire nose, of half the area of the cheeks, and of a portion of the forehead. It is not surprising that healing, either primary or secondary, failed under such circumstances. But it is hard to understand why the injured tissues should have become so sluggish and should have so persistently refused to granulate.

I should not operate in another similar case save by a formal rhinoplasty. I should remove as much as I could of the diseased skin as well as the tumor, and take a sufficiently large flap from the forehead, or two flaps from the cheeks, in order to fill the defect. Or again, I might attempt the covering of the nose by a flap derived from the arm. But the attempt to obtain a satisfactory result by using the diseased skin for flaps is, in my estimation, useless. In the cases that have been successfully done in this way the involvement of and change in the glandular structures of the skin must have been much less profound than in mine.

---

### A CASE OF RHINOPHYMA.

By Dr. A. H. OHMANN-DUMESNIL, of St. Louis, Mo.

Rhinophyma is by no means a rare condition, and from this fact it would be safe to assume that its successful treatment should be clearly and definitely laid down. Yet the records do not seem to justify such a conclusion. When you take into consideration the total number of cases and those which are operated upon, the percentage of the latter is not so large as we would be led to expect. Furthermore, those who do operate seem to have either no desire to report their results or have a reluctance on account of the imperfect condition which follows; so that, taken altogether, literature is far from teeming with such reports. This is one of the reasons why I have ventured to give a brief account of a case in which the final outcome was such as to make it worthy of a recital.

In general it may be premised that the *fons et origo* of rhinophyma, acne rosacea, is by no means the easy disease to cure which we are led to believe were we to be guided by the generalizations of those who have written text-books upon dermatology. We find cases which are of the most stubborn character and characterized by a chronicity which is disheartening to the patient and physician alike. When we have added to this the aggravation produced by the indulgence in alcoholics, we have a still more complicated state of affairs. The patient, despairing of ever getting well and clinging to his alcoholic habits, will in a certain length of time find that he has acquired that peculiar hypertrophy of the cutaneous structures of his nose which is known as rhinophyma, the pfundnase of the Germans, the degree of deformity differing widely in different cases, but being of such a marked character as to attract the attention of everyone.

The tendency which exists to the formation of dense fibrous tissue does not seem to be uniform. In some it ceases after a certain length of time, and a sudden standstill takes place. In others it continues to grow, slowly, it is true, until a deformity supervenes which is truly appalling in its dimensions, the pendulous nose, with its rugous, shining, red surface, gaping orifices and lobules which have been so graphically represented. I have never seen this state of affairs except in men, and these were past middle life and known as "stiff" drinkers, upon whom the condition had crept unperceived, so gradual was the process in its evolution. A peculiarity I have also noticed is that they are generally averse to any form of treatment.

I will not attempt to give a description of rhinophyma, for its characteristics are so well known to dermatologists that it would certainly appear as a work of supererogation. There is but one point to which I desire to draw attention, which is that, in general, we may divide the trouble into two varieties, viz., that in which we find one general hypertrophic mass, and that in which there are distinct lobes formed which are comparatively widely separated and markedly distinct. This difference has some little importance as bearing upon the treatment, and possibly also upon the pathological evolution of the mass. Not only this, but it may pos-

FIG. 1.—RHINOPHYMA.

FIG. 2.—RHINOPHYMA.

sibly have a further bearing upon the histological findings in the different forms, and there is a possibility of opening up a new field of investigation for pathologists, as I will endeavor to point out as I get further along in this paper. The entire subject is one replete with interest to the practicing dermatologist and offers an interesting field for more extended observation and study, not to mention more improved methods of treatment for the purpose of attaining final results of a successful nature.

The case which I am about to describe is one which possesses certain features of interest, both from a clinical and a pathological point of view. Moreover, the result of the surgical measures adopted is such as to prove encouraging in the treatment of future cases. So far as the pathological condition observed is concerned, it is one which has hitherto not been published, so far as I have been able to determine, and it is one of more than passing interest in regard to the processes which occur in the integument, for the anatomical groundwork of the skin itself is a *sine qua non* of the changes which are observed. Without any further preliminary remarks I will proceed to relate the salient features of the case, as well as to outline the principal steps of the operation which proved so successful in its final result:

*Case 1.*—Mr. X., about 72 years of age at the time he sought relief for his trouble (1890), was of a robust constitution and had always enjoyed the best of health. He had been in the habit of indulging in alcoholics, this being in a large measure due to his occupation, which was that of a saloon keeper. This indulgence occasioned an acne rosacea, to which he paid but little attention, as all those similarly affected are prone to do. He first noticed an enlargement of his nose in 1884, but did not pay much attention to this, regarding it as a very trivial matter. This enlargement, however, progressed slowly but steadily, and he was finally forced to seek relief, not on account of its appearance, but rather for the inconvenience occasioned, which is one that, to my knowledge, has not been mentioned heretofore by any author. The hypertrophy was of such a character, and so much tissue was developed in consequence of it, that its mass became a positive weight and pressed perceptibly upon the nostrils, forcing all the breathing to be made by the mouth, a condition which was but uncomfortable at first, but finally became intolerable.

When the patient was first seen he presented the following appearance: His general condition was that of good health, with a tendency to be stout. His complexion was florid and hair gray, a sparse beard occupying the lower part of his face. He had a look as of one who has lost sleep and is worried. In fact, his countenance did not express that ease which one would expect to observe in an individual of his build and in his social condition and circumstances. His nose was enormously hypertrophied, constituting a veritable tumor. The mass consisted of three principal lobes, well defined from each other, as shown in Fig. 1. There were two lateral lobes and one central, attached at their bases by what appeared to be rather long and narrow pedicles. Each lateral mass was pear-shaped and the central one had much the appearance of an inverted pyramid. Taken altogether, the entire growth would make a large handful and the entire weight was very nearly 2 pounds. The surface of the integument appeared coarse and irregular, the skin being notably thickened and the openings of the sebaceous ducts patulous. To the touch the mass felt hard and to a certain degree it was insensitive. The color was of a violaceous tinge, inclining to a red, and the entire surface had a shining appearance. The upper lip was completely hidden by the mass, and even the lower lip was encroached upon, rendering speech somewhat indistinct. When breathing was attempted through the nostrils it almost immediately resulted in the performance of that act through the mouth.

It is self-evident that medical treatment in such a case will never prove of any avail; the removal of the entire mass by the knife is the only course to pursue, as I will endeavor to show further on, and this course was resorted to in this case. The operation performed was about as follows: The lateral lobes of the tumor mass were removed, a small flap of the integument of each being left in order to cover the denuded surface. In each case this flap was obtained from the lower portion and was shaved thin and then turned over and up so as to bring the line of stitches at about that portion of the nose which corresponds to the sulcus of the ala. In the case of the middle lobe the same course was pursued, and of course the line of sutures was directly across the nose. The dissection of

the skin flaps was very carefully done so as to have as thin an integument as would be consistent with the proper nutrition of the parts. The stitches were fine and numerous, so as to avoid a scar as much as possible, a result which was pretty well accomplished, as may be seen in Fig. 2, representing the case after recovery. Union took place by first intention. This may have been due to the fact that after the sutures had been made the dressing which was applied consisted of iodoform collodion. A slight deformity, one, however, which would hardly be noticed, and which could hardly have been avoided under the circumstances, occurred. This consists in a very slight tilting up of the openings of the nostrils, due, no doubt, to the contraction of the tissues during the process of cicatrization. As I have stated, it amounted to but little, and merely points to the necessity of allowing for contraction of the integument as well as of scars in these cases as in all other plastic operations. At best, however, it is quite a difficult matter to estimate exactly the amount of skin required in plastic operations of this character, and in such cases as the one before us the exercise of a little economy is preferable to the exhibition of too much generosity, as any redundant tissue might be liable to take on the hypertrophic process rapidly and lead to a partial, if not a total, reproduction of the original trouble. The difference not only in the appearance of the purely physical portion of the face but in the expression indicative of the patient's morale is so evident upon comparing the two pictures representative of his state before and after treatment that comment is superfluous.

Before proceeding to a consideration of the pathology of the disease I desire to say a few words in regard to the operative measures employed. In the ordinary treatment the thermo-cautery is used for the purpose of provoking cicatricial contraction throughout the mass and thus gradually diminish the size of the tumor. This method is one which is very long; it is also very painful and it does not give a nice, even result.

Dr. Dupré speaks of the manner in which he operated upon a patient in the following words.\*

The patient being under an anæsthetic, I removed from the immense tumor slices of the fleshy mass as one might slice a melon. I then sutured the raw surfaces and cauterized them with the thermo-cautery, and I made a sufficient number of incisions into the lardaceous tissue to bring the organ down to its primitive volume. The sutures were removed the fifth day. Two months after the operation we see that the mass has continued to diminish until scarcely a trace of its former condition remains.

Ollier† has practiced decortication by means of the thermo-cautery, the advantage claimed being the absence of all hæmorrhage and a comparatively rapid result. Berger‡ has a preference for the knife. He simply removes the lobes and obtains good results. Hicquet§ claims to have obtained good results by making punctate cauterizations with the galvano-cautery. Franz Wings|| describes a method which consists in removing the entire tumor and leaving only so much as will insure a growth over the denuded portion. This growth is large and is caused by the projecting portions of the sebaceous glands, their ducts aiding in the proliferation of epithelial tissue.

Of course, these methods, which are but a moiety of those employed, are no doubt of value; but shelling out the tumor is, in my opinion, the procedure that is most likely to yield the best cosmetic results. Necessarily great caution must be observed, not only in removing all the hypertrophic tissue but also to avoid cutting away too much from the under surface of the integumentary tissue. The proper method of accomplishing this is by cutting away a sufficient quantity so as to leave the smallest sebaceous glands intact. In this manner there is much less liability of a recurrence of the disease, and a condition closely approximating the normal is retained, so far as the secretion of the glands is concerned.

|| Das Rhinophyma und seine Behandlung. Inaug.-Diss. Berlin, 1889.

I will not enter into a consideration of the causes of acne rosacea and rhinophyma, as it would make this paper reach an inordinate length, but will rather consider the pathology of the peculiar process spoken of, and will present some peculiarities which I had an opportunity of noting in the specimen obtained from the case which has been described above. Upon ocular examination of the excised portion it appears distinctly fibrous, its density being quite well marked. The skin proper covering this hypertrophied part is thin, being more marked in this respect in the side lobes than in the central one. The openings of the sebaceous ducts are large and patulous, more especially in the central lobe. In one lobe there appears what seems to be a large retention cyst, nearly a half inch in diameter and filled with fatty material somewhat liquefied. A number of smaller cysts of the same nature can also be made out in the same lobe, as well as in the other lateral lobe, but can not be made out in the central one. These are all clearly sebaceous cysts which were originally sebaceous glands which have become distended by the pressure exerted upon their excretory ducts. Here and there may be seen quite plainly enlarged blood vessels in cross section, and some portions of the structure seem to indicate the presence of some degenerative process. Upon attempting to cut the tumor it gives the same sensation as when a fibroid is resected. Such is a brief outline of the microscopic appearance presented.

Before detailing the microscopic findings it may be as well to give a brief summary of the descriptions furnished by a few competent authorities. Their accounts seem to differ somewhat in details and it is not unlikely that this discrepancy is due to the fact that each one was necessarily limited to a few specimens in making his observations. In the case which I have related the various appearances presented agreed pretty well with the descriptions given, so that it may be safely concluded that the microscopic anatomy, while different in minor details, is of a pretty uniform character. I propose, however, to call attention to one exceptional condition which I have failed to note in the published accounts.

Hans Hebra,\* who wrote an elaborate paper on rhinophyma, including its microscopic anatomy, states that the sebaceous glands are very numerous and quite large, forming a very prominent element in the pathological condition which is present. It is his opinion that this condition of hypertrophy of the glands is secondary to the connective tissue hypertrophy, which by its development occludes and cuts off portions of sebaceous glands, which then go on secreting and thus produce a retention of sebum, which in turn acts as an irritant, and thus stimulates the tissues to further hypertrophy. Biesiadecki† also found distension of the sebaceous gland, accompanied by hypertrophy. He further noted the enlargement and new formation of blood vessels, not only in the superficial tier, but also in the branches arising from the corium. Piffard‡ examined a case operated on by C. Wagner, and found that the horny layer of the skin was scanty, but the rete mucosum thick, with well-formed cells. The papillæ were enlarged in length and breadth, and contained round and fusiform cells. Some sebaceous glands were normal; others were undergoing degenerative changes. The corium itself was greatly thickened and presented the appearance of formed tissue. Bulkley,§ in describing a case, states that the tumor is composed of closely woven connective tissue fibres, embracing relatively large blood vessels; the rete and epidermis are unchanged, and in this specimen there appears but a single sebaceous gland, not greatly enlarged. Blood vessels consist of arteries with hypertrophied coats and dilated veins. There is more or less small-cell infiltration also seen in the tissue, together with many embryonic cells. In the figure which is given (Fig.

\* Vierteljahresschrift für Dermat. und Syph., Heft 4, 1881.

† Pathologie und Therapie der Hautkrankheiten, von M. Kaposi, 1883.

‡ Archives of Clinical Surgery, Vol. I, p. 21.

§ Acne and its Treatment, 1885.

26, p. 216, by Elliot) the papillæ have all disappeared, numerous enlarged blood vessels are shown, the rete is distinct, and the stratum corneum somewhat thinned. No sebaceous glands appear, and a small-cell infiltration is shown here and there throughout the fibrous tissue of the tumor, this tissue appearing to be one with the corium. Franz Wings\* gives a very elaborate account of the microscopic investigations made by him. He finds that the epidermis undergoes no changes, nor are there any perceptible alterations to be seen in the subcutaneous connective tissue. It is in the corium that we are to find the hypertrophy. It is so great that in some places he saw the apices of the unaltered papillæ flattened by the pressure exerted by the fibrous tissues lying underneath. The number as well as the relative size of the sebaceous glands appears increased. The blood vessels are also enlarged and more numerous. The mass is composed of white fibrous tissue, with a strong infiltration of small, round cells. In many places, throughout the connective tissue, cells and nuclei could be found. He attributes the formation of the retention cysts to the constricting force exerted by the fibrous hypertrophy, which cuts off the excretory ducts from the acini and at the same time obliterates the opening by which the contents of the latter escape.

In making a microscopic examination of the parts removed in the case given I limited my sections to one lateral lobe, and found that almost each one differed from the other in some particular. All, however, agreed in some general characteristics, which I will proceed to briefly enumerate. The stratum corneum appeared normal or very slightly thinner than normal, but preserved its characteristics. The stratum mucosum also appeared normal, the papillæ being possibly slightly elongated in some specimens. The cellular structure, however, is quite marked and distinct, the pigmentary layer being remarkably prominent. The corium seems to have disappeared and merged into a mass of fibrous tissue, which extends downward for quite a distance until it is lost in the subcutaneous connective and adipose tissues. Large blood vessels are to be seen throughout the mass, and cross sections show that a distinct hypertrophy of their walls has taken place. The pigment which is marked in the columnar layer of the papillæ and also in the corium immediately surrounding them is not confined to these localities, but may be found diffused near the apices of the papillæ as well.

The sebaceous glands vary largely in numbers in different sections. In some they can not be made out at all, or are very sparsely distributed. In others again they are numerous beyond the normal, and in a few I have found them so abundant that they touched each other. In all cases in which they were found they were well filled with sebaceous material and their ducts opened freely upon the external surface of the skin. The most diligent search failed to reveal the existence of any in which the duct still existed but had been occluded. On the other hand, however, cystic bodies filled with fatty material could be distinctly made out. In each instance the characteristic morphology of the sebaceous gland had disappeared. A lining membrane of a more or less homogeneous character inclosed in a dense fibrous envelope could be seen. Some cellular débris could be made out clinging to the internal capsule of the cyst, the remains, no doubt, of the secretory cells, which continued to furnish the material which contributed to the enlargement of the cyst.

The coil glands are well developed in some parts and do not seem to have at all failed in their functions, if we are to judge from their dimensions. A peculiarity that is to be noted in connection with these organs is that the coil retains its relative position in the subcutaneous adipose and connective tissue. The strangest circumstance in connection with the whole matter is that the duct persists throughout the entire hypertrophic mass in an apparently uninterrupted and continuous tube, lined with columnar epithelial cells. This is certainly something

---

\* *Loc. cit.*

unusual in view of the fact that the ducts of the sebaceous gland are not spared and that the pressure of the hypertrophied tissue has so thoroughly and markedly flattened the apices of some of the papillæ. The subcutaneous fat is about normal in appearance and quality, having suffered no apparent change. In the body of the fibrous mass, however, are to be seen at rare intervals, it is true, fat cells, each one of which appears to be isolated from its congeners. It was the occurrence of this strange sight that first drew my attention more particularly to a closer examination of the growth. Their appearance is strongly suggestive of a derivation from the subcutaneous adipose tissue, yet their distance from that structure is so great that we are forced to one of two conclusions. As has been mentioned, the gradual formation of the fibrous tissue of the tumor has a certain strangling effect upon structures lying in its vicinity. If these structures have a sufficient amount of resistance the slow pressure acts in the manner of a stimulus, and the result is a compensating hypertrophy. On the other hand, if not endowed with sufficient resisting power atrophy is produced, and the result becomes evident. An example of the former is seen in the hypertrophy of the blood vessels; of the latter, in the development of the retention cysts which are seen. To recur to the possible explanations which may be given for the occurrence of these isolated fat cells, we may assume that in the process of strangulation of the ducts of the sebaceous glands some of the fat cells of the sebum still contained in those ducts may have been caught in the meshes of the fibrous tissue. This would seem to be borne out by the fact that the solitary fat cells observed are smaller than those of the subcutaneous fat. Another appearance which would appear to lend weight to this view is the occurrence of irregular masses, which, while not well defined, are very suggestive of sebum, but they are very probably artefacts produced by the process of cutting sections, the knife possibly dragging some sebum over the section. This is rendered the more probable by the grumous appearance which each mass presents. The only other explanation which occurs to me is that during the progress of the hypertrophy a *columna adiposa* such as described by Warren\* should have been inmeshed in the fibers of the fibrous growth, and in that manner some fat cells might have been isolated. It is true that Warren states that we only find these fat columns where hair exists, but lanugo hairs are by no means uncommon on the nose, and well-developed hairs are frequently seen on the tip of the nose in men. This very circumstance of the connection of these columns of fat with hairs would seem to lend additional weight on account of the sparse number of those hairs and the correspondingly small number of isolated fat cells which is noted.

The question which would naturally arise is why these cells do not become absorbed through the pressure exerted upon them. This is a difficult question to answer and can only be accounted for on the supposition that some have more resisting envelopes, and their oily contents rendering them elastic they successfully oppose the pressure which is exerted.

The pathological anatomy of rhinophyma is a subject which is far from being exhausted, and, from my limited observations, I am inclined to believe that it promises to open up a large and interesting field for further and more elaborate investigations.

#### DISCUSSION.

Dr. RAVOGLI, Cincinnati. Although the essayist must be congratulated for the excellent results obtained in the referred cases, I believe, however, that in rhinophyma we can not establish a method of operating, and we have to adapt ourselves

---

\* J. Collins Warren. *Columnæ adiposæ*, etc. Cambridge, 1881.

according to the features of the cases. In regard to the etiology, I would remark that rhinophyma is the last stage of acne rosacea, and although I never had to do with such an advanced case, yet I have had many cases of acne rosacea in different stages. The abuse of alcoholic liquors is without doubt an efficient cause of this disease, but yet I have found cases of this disease in ladies and gentlemen who never had tasted liquor in their lives. In these cases I found that they had suffered with dyspepsia and catarrh of the stomach, which often is the cause of the acne rosacea. Seborrhœa is the most prominent character of acne rosacea, with stasis of the blood in the vessels. I think that with a well-directed treatment of acne rosacea we can prevent the progress of the disease and the lost hypertrophic condition of the tissues, subject of the proper rhinophyma.

Dr. OHMANN-DUMESNIL, St. Louis. So far as the occurrence of rhinophyma being confined to men, it is simply a personal experience. There is certainly no doubt that it is a consequence of the process whose inception is manifested by acne rosacea. We find acne rosacea in women, it is true, as well as in men; but, in the latter, indulgence in alcoholics brings about the peculiar hypertrophy. Many other causes operate to produce acne rosacea, but so far as my experience goes alcoholic indulgence is the active factor in the production of rhinophyma. The operation which I have described and which proved so successful was one adapted to the particular case in question. No hard and fast rules can be laid down in these cases of plastic surgery, and the operative measures must certainly be governed by the peculiarity of each case.

Dr. GOTTHEIL, of New York. I believe that rhinophyma must be regarded as a hypertrophy of all the layers of the skin, but more especially of the connective tissue of the corium. The vessels also are markedly increased in number, and their walls are thickened; but the most characteristic change, next to the connective-tissue increase, is the enormous enlargement of the sebaceous glands and the dilatation of their ducts. These latter are often 2 to 3 lines in diameter at their mouths, and a soft and altered sebum continually exudes from them. Under the influence of any irritation these glands become suppurating sacs, and this renders plastic operations which look to a primary union of the parts so difficult. The case of which I show you here a moulage, and upon which is based the paper just read to this body, was by no means as extensive a one as that of Dr. Dumesnil. The operation consisted of an elliptical excision by which the entire central lobe was removed. The skin was then dissected off the enlarged alæ, masses of connective tissue and fat were removed from them, and the flaps carefully united in the middle line. Union did not occur, the sutures ulcerated out, and the entire wound became infected from the suppurating glands. A large defect was left that granulated up only with extreme difficulty. Stimulating applications of the most varied nature were used, and finally, after several months of effort, the defect closed with a broad scar. Another point that I would call attention to is the relationship of this hypertrophy of the skin of the nose to lepra Arabum. The processes are undoubtedly allied ones, and possibly identical in some cases, and it would be interesting to know the condition of the lymphatic system in rhinophyma.

Drs. Gottheil and Alfred E. Regensburger asked the reader of the paper if the disease was not an aggravated or exceptionally developed form of acne rosacea.

The reader replied that it was not.

Dr. Regensburger also asked Dr. Ohmann-Dumesnil how long since he had seen the patient after the operation, and if it was still a good result.

Dr. Ohmann-Dumesnil replied that he saw him a few weeks ago and that the result was still as perfect as the photograph, which he showed, depicted it to be.

In the discussion which followed Dr. Regensburger asked Dr. Ravogli if in his case the patient was suffering from any disturbance of the generative functions or organs.

Dr. Ravogli answered no ; not as far as he was aware of.

---

## LUPUS; ITS EXTIRPATION, AND REPORT OF CASES.

By B. MERRILL RICKETTS, M. D., of Cincinnati, Ohio.

So much has been said about this disease during the last three years by men who have spent the greater part of their time, not only in treating it, but in studying its pathology, that it might seem preposterous for one with limited advantages to offer anything new concerning it. The ravages that it produces and its persistent character have made not only the sufferer but the surgeon desperate. Considered in the light of experience it is not strange that the treatment of to-day gives but little relief. Koch has, perhaps, more nearly approached a panacea for lupus than any other investigator. Whether or not the future treatment and consequent good results are to be obtained by following up his principles is yet a question. That the disease is both local and constitutional there seems to be no doubt, and when a lesion is cured the preponderance of evidence is that it was a mistaken diagnosis; that it was not lupus, but some other disease of less virulency. However this may be, we must necessarily depend to a great degree upon the clinical history and appearance of the lesion. While we depend upon the microscopical investigation, we must not accept the picture as one to be recognized at all times. While I believe that the bacilli when found indicate a certain disease, I can not accept a statement that it is not that disease because the bacilli can not be found. In other words, I am not ready to accept the microscopical investigation as infallible. I would rather depend upon the clinical history and appearance in making a diagnosis of lupus than the statement of any microscopist. Neither do I believe in the infallibility of any diagnostician. Anything may be deceptive; just so may a person be deceived.

The rarity of the disease and the few cases which the average practitioner has the opportunity of seeing, especially outside of the larger cities, is no doubt the occasion of mistaken diagnoses. It is not supposed that a man who sees a great many cases of disease is as likely to be mistaken in his diagnosis as one who sees but few. Consequently we must rely mostly upon the statement of those with greatest experience, especially in differentiating lupus from other diseases. My experience has been somewhat limited. I have seen in public and private practice about 65 cases, but I was early convinced that treatment of any kind availed but little. This naturally led me to resort to more desperate means than was usually employed by those with whom I was associated. Scarification, curetting, cauterization in the various ways, the application of caustics, such as nitrate of silver, carbolic acid, etc., all convinced me that the disease, when possible, should be excised, or that constitutional treatment was necessary. Constitutional treatment having been found useless there was left, to my mind, nothing but total extirpation. Unfortunately the disease occurs mostly about the face, eyelids, nose, ears, and lips, places where extirpation is made with the greatest difficulty and where the greatest deformity is the result. I believe that the extirpation of lupus is about as certain, when done in its earliest stages, as some of the forms of epithelioma and sarcoma. The question arises, when does it become constitutional, and to what degree may it become constitutional when extirpation would be useless? It is also important to determine that degree in any of the malignant growths. If lupus is found upon the finger we would not hesitate to amputate that finger;

if lupus were to appear upon the hand we would naturally resort to all means of treatment to save the hand. Would it not be better to remove the hand early in the progress of the disease? We know that the removal of a finger affected with lupus has cut short the disease, and that the patient has lived for years without any recurrence. Now, if this is so, why is it not rational surgery to extirpate any lesion that may appear upon any part of the body?

The means that we now have at our command in restoring parts with both single and double pedunculated grafts should encourage both the operator and the patient in resorting to early surgical interference, no matter upon what part of the face the disease may be found. The dread of suffering, of taking an anæsthetic, and of being deformed, I might say, is the occasion of so much procrastination, not only in the treatment of lupus, but all other diseases. What are we to do with these unfortunate creatures when they present themselves to us for treatment? Are we to tell them that nothing can be done; that it is folly to attempt to relieve them? Believing as I do, that all diseased tissue should be removed when possible, I have been led to extirpate lupus on several occasions with most gratifying results. So far I have not made any classification of the disease. It is, however, necessary, in order that we may simplify matters and talk more intelligibly. I have treated the two forms of lupus (*lupus vulgaris* and *lupus erythematosus*) in the same manner.

Of the former I have seen 42 cases; of the latter 23.

*Case 1.*—Female, æt. 67, single, white, American, poorly nourished, posterior spinal curvature, most excellent habits. There had existed for about eighteen years a lesion upon the left cheek on a line with the lower edge of the ear. This was red, and had gradually increased in size, with here and there a tubercular nodule, giving all the characteristics of *lupus vulgaris*. There were also cicatrices in the surrounding tissue, showing that some of them had at various times healed and given place to more recent ones. She consulted me to see if something could not be done. My diagnosis being that of *lupus vulgaris*, I offered no suggestions than the total extirpation of the diseased tissue. This she readily consented to, and under the influence of cocaine, subcutaneously, I removed what I believed to be the entire amount of tissue involved. Union was primary, and she was discharged at the end of five days. Within the course of six months it was evident that the disease had not been entirely removed, and I again excised it under the influence of cocaine, with the same good result so far as healing was concerned. She was discharged at the end of six days, and we again felt that we had done all that was necessary to rid her of the annoyance. At the end of twelve months the disease again manifested itself, and I concluded to excise it as before, under the influence of cocaine, curetting the surface thoroughly and applying arsenious acid in combination with cinnabar. This was done, and an extensive sloughing was the result. It required several weeks for the wound to heal by granulation, her health in the meantime being somewhat impaired. However, by judicious management and her ability to take the requisite amount of food her recovery was uninterrupted and she was discharged at the end of eight weeks. There was no family history of tuberculosis in this case. The spinal curvature was attributed to an injury. However, I am inclined to believe that the subject was a tubercular one, without any special manifestations. She died three years after from an attack of acute gastritis, the lupus never having manifested itself again in the slightest degree.

I report this case to show the importance of persistency in the treatment, not only of epithelioma and other malignant growths, but that of lupus in any form. What the result would have been at the end of ten or fifteen years, had she lived, I am, of course, unable to say.

*Case 2.*—Female, æt. 70, widow, white, German; in a most excellent state of health. This patient consulted me in January, 1889, for a small lesion upon the margin of the right nasal ala, which had existed for eight years. The disease had been slow in progress, giving her no special discomfort or annoyance. It had, however, made inroads upon the wing, involving a surface about one-half of an inch along the lower margin, extending about three-eighths of an inch upward along the side of the nose. My diagnosis was *lupus vulgaris*, and my suggestion was its total extirpation. This was consented to, and the operation made under the in-

fluence of cocaine subcutaneously. A sliding flap was taken from the cheek and placed in the intervening space, allowing the lower margin of both remaining pieces of the ala to form the lower margin of the wing. Primary union was the result, and the patient is to-day entirely free from the disease. This has now been fifty-four months. Possibly there may yet be a recurrence, but has not the result proved that the operation was justified? There was no indication of tuberculosis in this case, nor was there any history of its having existed in her family.

*Case 3.*—Male, æt. 48, white, Irish, excellent health, weighing about 165 pounds, laborer, irregular and dissipated habits. He consulted me in July, 1887, for a lesion upon the left side of the nose, about midway between the inner canthus of the eye and lower margin of the ala, which had existed for eleven years. The disease had been slow in its development and there was no special discomfort or pain. It gave all the characteristics of lupus vulgaris. I advised its total extirpation, and made the operation on the following day under the influence of cocaine subcutaneously. I removed a piece of integument about 1 inch wide and  $1\frac{1}{2}$  inches long, cutting through the cartilage into the nasal cavity. A sliding flap was made, filling the space perfectly and resulting in primary union. This has never recurred, and I feel sure the man is as exempt from a recurrence of this disease as if it had been epithelioma. He did not give any history of tuberculosis except on the father's side, in which case the patient's own uncle died from what was considered consumption following pneumonia.

*Case 4.*—Female, æt. 63, single, white, American, in good health, weighing 120 pounds, consulted me in 1890 for a lesion upon the left cheek, just in front of the ear, covering a surface about  $1\frac{1}{2}$  inches in diameter. This answered the description of lupus erythematosus, and it was so classified. It had existed about twelve years without giving any pain or discomfort, except a burning sensation; itching, and extensive exfoliation of the cuticle. It had gradually become larger, and caused considerable anxiety on the part of the patient and her friends. Extirpation was suggested and readily consented to. This was done after thoroughly anæsthetizing the field of operation with subcutaneous injections of cocaine. The edges of the wound were coapted with silk sutures and primary union secured.

I cut in this, as in all other cases, far beyond the line of demarcation, and removed the entire integument and cellular tissue overlying the muscular structures. There has not in this case been any return. This is the only case of lupus erythematosus in which I have been able to make the operation of extirpation, and I am quite sure that I would earnestly advise such a course, although my experience is limited to one case. True, where the disease has been allowed to progress to an extensive degree over the cheeks or about the eyelids and lips, or nose, or ears; in other words, where the disease has been allowed to extend to such a degree that extirpation would cause great deformity which could not be prevented or overcome by grafting, one must necessarily hesitate in resorting to such radical measures.

In conclusion, I wish to say that I would not hesitate to extirpate lupus tissue in any case where the parts may be restored in any way whatever. Neither would I hesitate to amputate a finger or toe upon which either one of the two forms of lupus existed. There are cases, however, where it might be unwise to extirpate the lesion. Even in cases of multiple lupus I would advise their excision if the areas affected are small. Whether this plan of treatment should be limited is a question with the operator. So far I have seen but three or four cases of multiple lupus. I am quite sure that in each case good would have resulted from the extirpation of the various lesions which either one of them possessed. Would it not be well for us to call a halt in saying that there is nothing to be done in cases of lupus? I believe that the pendulum should be swung in the opposite direction, and that the preponderance of evidence at the present time fully justifies this statement. Even though the disease should recur, it is not until quite a length of time has elapsed. I believe that the end justifies the means, and that it is humane to subject these unfortunate patients to the operation of extirpation, even though the relief be but for a short time. This, of course, requires more judgment in cases of lupus upon the various parts of the face. I have presented the subject to see if it can not be brought more prominently before the surgeons; that is, the operation of extirpation. I think the cases that I have reported and the subsequent good results from extirpation

fully substantiate what I have said. Possibly I am deceived in my diagnosis, but I am thoroughly convinced in my own mind that I am not. I do not mean to be understood as saying that the disease will not recur in either one or all of the cases; surely I could not be so foolish as to say that. I propose to extirpate lupus, if possible, wherever found. I believe that if this is done a great deal of suffering, disfiguration, and I might say loss of life will be prevented.

It would give me great pleasure if those who have been interested in this procedure would address me upon the subject. By doing this I hope to tabulate the various cases in which the operation has been resorted to.

### GLYCOSURIA AS AN ADDITIONAL SYMPTOM INDICATING THE NEUROTIC ORIGIN OF DERMATITIS HERPETIFORMIS (DUHRING).

By JAMES McF. WINFIELD, M. D.,

*Attending Dermatologist to the Kings County Hospital, the Long Island Hospital, O. P. D., Assistant to the Chair of Skin Disease at the Long Island College, etc.*

Many cases of dermatitis herpetiformis have been reported by Elliot, Brocq, and others, pointing to some severe nervous shock as the essential etiological factor in the production of this interesting cutaneous disease. But in the writings of each no mention is made of any change in the urinary secretions. In the following cases glycosuria was present to a greater or less extent, and in all of the cases personally observed, irrespective of those herein reported, the original and recurrent attacks followed some unusual mental exertion or severe nervous shock, showing an intimate relationship between the advent of the eruption and the reception of the shock.

*Case 1.*—Mr. S., aged 29 years; strong and well-developed man; no history of any specific taint; habits temperate; skin dark, but perfectly healthy as to texture, etc. During a severe and prolonged mental strain (endeavoring to abort a strike at a foundry in which he was a foreman) he noticed a few painful, itchy vesicles over the neck and right ear. These rapidly multiplied until the shoulders, arms, chest walls, buttocks, and thighs were invaded. At the time of consultation the following was observed: The parts enumerated were covered with a profuse eruption of a multiform character, chronic, subacute, and acute. There were papules, vesicles, and pustules scattered throughout the entire portion affected. Frequently the three would be closely grouped together in a circumscribed patch. In parts the arrangement and distribution closely resembled herpes zoster. The vesicles were of various sizes, many of them being minutely small, while others were as large as pemphigoid bullæ. The pustules dried into dark-brown scabs.

At first the patient complained of severe burning in the diseased skin, but after the eruption had existed for two days this was accompanied with itching, which grew more intense as the process continued. The treatment was wholly palliative, bromide and chloral to quiet the nervous irritation and to produce sleep; external lotions and ointments containing antipruritics to allay the itching. All through the illness there had been polyuria. On account of this symptom, and at the suggestion of Dr. Sherwell,<sup>1</sup> who had seen the case in consultation, the urine was examined, with the following results: Color light; specific gravity, 1.030; nothing special by microscope; test for albumin negative. On testing for sugar it was found at all times, in varying quantities from a trace to as high as 5 per cent. With this clew the treatment was directed to the relief of the diabetic condition. Diet was regulated, mental worry removed, and the administration of codeine and the bromides, and tonics containing arsenic. The external treatment was soothing; the patient rapidly improved, and was dismissed cured in about one month from the advent of the disease. Fourteen months after he again presented himself with the same cutaneous manifestations in a less degree, which had again followed mental worry. The urine, being examined, was found to contain about 1

<sup>1</sup> Dr. Sherwell referred to this case at the twelfth annual meeting of the American Dermatological Association, 1888.

per cent of sugar. Beneficial results were obtained by about the same line of treatment as in the preceding attack. Since then the patient has avoided mental shock and worry and there has been no recurrence of the cutaneous disease, now nearly six years.

*Case 2.*—Boy, aged 13. After a severe fright, voided large quantities of urine which was found to contain traces of sugar. A short time after the reception of the nervous shock erythematous patches appeared on the neck, buttocks, and inner side of the arms and thighs. The patches became thickly studded with papules which rapidly developed into vesicles and pustules, which finally dried into dark-brown scabs. The treatment was to quiet the disturbed nerves, soothing applications to the skin lesion to subdue the intense itching, which was the most annoying symptom, antipyretics for the fever, and finally tonics. After two or three relapses the patient became fully convalescent.

*Case 3.*—Mrs. M., a slight but well-built woman; mother of three children; temperament nervous and hysterical; general health always good. Before the cutaneous process began she had been subjected to excessive mental anxiety and shock, superinduced by the illness and death of her youngest child. The eruption was principally over the neck, chest, and thighs, presenting the typical picture of dermatitis herpetiformis, as described by Dr. Duhring. There was no polyuria except just after the death of her child, which was probably wholly hysterical. However, the urine was found to contain sugar in small quantities. The treatment was quite similar to that of the first case, but in spite of physical improvement the mental state remained bad. The cutaneous condition would improve for a few days, followed by a relapse, successive crops of papules and vesicles appearing at short intervals. The patient was advised to seek change of scene and climate, when slow but permanent convalescence was established.

*Case 4.*—Mr. S., aged 40 years, of a highly nervous and excitable temperament; worries about the slightest things. Had been given to excesses in early life. The eruption, which had existed for over a year, consisted of vesicles and papules on the neck and shoulders. There was also a papulo-vesicular erythematous plaque over right buttock and thigh. Frequently during the course of the disease the small vesicles would coalesce and large bullæ would be the result. There was itching at all times, being more intense during the acme of the eruption than in the beginning or the ending of the outbreak. The initial attack followed anxiety over business difficulties. The urinary secretion was greatly increased in both the first and subsequent attacks; tests for sugar always revealed it in varying amounts. When the mental disquiet subsided the urine became normal and the eruption grew less, fresh exacerbations following the slightest anxiety or worry. The patient being easily discouraged and not receiving rapid results from treatment, became dissatisfied and consulted another physician, with what results is unknown.

These cases are interesting, inasmuch as they all present a symptom (glycosuria) which has not been referred to in any article on this much-discussed disease. It is not the object of this paper to consider *in extenso* the other clinical facts, but it is proper to refer briefly to the bearing of this symptom on the theory of the disease. Since the time of Claude Bernard the existence of a sugar center in the medulla oblongata has been generally recognized. It is further known that not only after direct puncture of this center, but also in some cases of general brain shock, and in even more localized sudden lesions in distant parts of the brain, sugar in the urine has been observed. Beyond the cases of direct injury to the oblongata, there is so little uniformity in the other cases of cerebral injury that it is impossible to draw any inferences from them bearing more closely on the disease under discussion, although the presumption is admissible that in all of them there is implication of the sugar center. Whether this represents a distinct mechanical irritation, as by pressure, or whether it be produced indirectly by influences from the higher centers related to the oblongata, is more properly a neurological point. It is sufficient that the facts are established and that they offer a reasonable explanation of the glycosuria following nervous shock in the four cases reported. The occurrence of sugar in the urine, coupled with the neurotic symptoms described by other observers, corroborates the view that the cutaneous manifestations of dermatitis herpetiformis are of nervous origin.

## ON SOME OF THE RARER TROPHIC LESIONS IN LEPROSY.

By BEAVEN RAKE, M. D., of London,

*Medical Superintendent of the Trinidad Leper Asylum; late Member of the Indian Leprosy Commission.*

Leprosy is a disease in which, if the patient lives long enough, the peripheral nerves are always found to be more or less infiltrated with new growth, associated with the presence of leprosy bacilli. Though for the sake of convenience it has been customary to classify the disease into the three divisions of tuberculated, anæsthetic, and mixed, a close examination shows that this classification is purely arbitrary, for, on the one hand, a case of tuberculated leprosy in its late stages shows infiltration of the peripheral nerves with the leprosy growth, thus producing the mixed form; and on the other hand, recent dissections by Gerlach<sup>1</sup> show that in anæsthetic leprosy the primary growth takes place in the skin around the nerve endings, extending afterwards up the branches to the main trunks. It thus appears that in both tuberculated and anæsthetic leprosy the skin is first involved, and that the question of implication of nerves is only one of degree. The nerves being thus involved sooner or later in all cases of leprosy, it would naturally be expected that various trophic lesions would follow. The more common of these, such as anæsthesia, ulceration, gangrene, and necrosis of bone, are too well known to require description; but I have thought that a short consideration of some of the rarer trophic changes may be of interest. I have used the word trophic advisedly, for though we can hardly regard the existence of trophic nerves as satisfactorily proven there can be no doubt that the changes about to be considered are dependent on disturbances of nutrition. Whether they are brought about directly by changes in special nerves supplying the tissues, or indirectly through vasomotor lesions, the point at issue is not affected, and the term "trophic" is a convenient and short one for working purposes.

The conditions which I propose to discuss to-day are: (1) Raynaud's phenomena; (2) Charcot's joint disease; (3) symmetrical bedsores; (4) perforating ulcers; (5) a condition resembling ainhum; (6) certain ophthalmic lesions; (7) zona.

## (1) RAYNAUD'S PHENOMENA.

In 1862 Raynaud described a condition which he called "local asphyxia and symmetrical gangrene of the extremities." He defined it as "a neurosis characterized by enormous exaggeration of the excito-motor energy of the gray parts of the spinal cord which control the vasomotor innervation." In a second thesis he maintained the following proposition: "There actually occurs in this malady spontaneous vascular spasm, inappreciable in the great vessels, but very obvious in arteries of small caliber." The symmetrical gangrene which sometimes occurs in leprosy is, as we know, associated with anæsthesia; indeed, it probably occasionally starts from slight injuries unwittingly inflicted on the anæsthetic extremities. Quite different is the condition described by Raynaud as preceding symmetrical gangrene, and called by him "arterial anæsthesia." The peculiar feature is that it is limited above by a line drawn on the same level all round the extremity. In leprosy the anæsthesia follows the distribution of certain nerves in the earlier stages, though later on it may become general. In the following case local asphyxia came on four years after the onset of the leprosy, and the two conditions went on side by side. The case has already been published<sup>2</sup> in full, so it will be sufficient to describe it briefly here:

*Case 1.*—Chevy A., aged 45, born in France, was admitted to the Leprosy Home on May 19, 1883, with anæsthetic leprosy of one year's duration. There were

<sup>1</sup> Untersuchungen über die Unabhängigkeit der Bildung Anæsthetischer Hautflecke von der Erkrankung Zugehöriger Nerven bei der Lepra Anæsthetica. Dorpat, 1890.

<sup>2</sup> Lancet, November 12, 1887, p. 958.

localized areas of anæsthesia on the extremities, but no contraction or ulceration. The anæsthetic skin was of exactly the same color as the unaffected skin. The disease remained practically stationary till 1886, when, on my return from Europe, I noticed a remarkable change. The following notes show the conditions October 1, 1886: The anæsthetic patches are of the usual white color; all the rest of the skin is of a dusky red. The skin thus presents the appearance of a mosaic, or of a colored map, the white patches being sharply defined against the surrounding dusky red skin. The congestion disappears under pressure. On drawing the nail across the skin, the dark color vanishes, then reappears, and afterwards a distinct bright-red wheal is observed. He says the congestion disappears when he bathes in the sea. He complains of much pain in the limbs, especially in the palms of the hands. The fingers are anæsthetic and become stiff. October 25: Gurjun liniment has failed to give relief. He says the fingers are stiffer and more painful. The left median nerve was therefore stretched under chloroform. On exposure it was found to be thickened. Some fluid was pressed from the nerve and examined, but no leprosy bacilli were found. October 29: He says there is a sleepy feeling in the palm of the hand, where there was formerly anæsthesia. When tested with the eyes shut, he refers the impact of a resistance to one side of the point actually touched. November 12: It is now raining and the color of the skin between the white patches has turned to a dusky reddish blue. He says the fingers feel cold, and that sometimes the skin is almost black during the rainy season. The temporary improvement in sensation noticed after stretching the median nerve has now entirely gone. February 14, 1887: He has been rubbing the arms with a 10 per cent solution of ichthyol in olive oil. The skin is a little light in color, but there is no change in the anæsthesia. March 14: The congestion of the skin is almost gone. He has had dysentery for the last month. April 16: He has been losing much bright blood from the bowel lately. A prolapse of the rectum was found with a congested ulcerated surface. Under chloroform the lower 2 inches were drawn down, everted, and cauterized linearly in the long axis of the bowel with a black hot wire. The mucous membrane was then rubbed over with fuming nitric acid and tannin applied. April 29: Since the operation he has passed a good deal of blood from time to time. This has been checked by enemata of nitrate of silver and of opium and by turpentine by the mouth. The violet color between the patches on the upper extremities have gone, leaving the skin of a dusky red color. From this time to his death hardly any more blood was passed, but diarrhœa was persistent. The turpentine was continued for some time, but eventually it caused retention of urine, and the bladder had to be emptied with a catheter. A trace of albumin was found in the urine. Toward the last fever came on every day at noon, and was somewhat relieved by ammonium picrate. The hands and feet became edematous. He died on May 19.

The autopsy showed 5 distinct abscesses in the liver, containing from 2 to 3 pints of pus. The liver weighed 83 ounces; the spleen weighed 18 ounces, and was hypertrophied; kidneys, 9 ounces; cortices somewhat thinned and granular; aorta very atheromatous. No recent hæmorrhage or ulceration was found in the rectum, the ulcers appearing to be cicatrized, but in the rest of the intestine were numerous sharp-cut ulcers. The median nerves were thickened, but no difference was found between that which had and that which had not been stretched. The superior cervical ganglion of the sympathetic and the ganglion of the vagus were dissected out on the right side, but no naked-eye change was observed. Under the microscope, however, numerous bacilli, both free and in cells, were found in the sympathetic ganglia and also in the median nerve.

The strange feature in this case was the appearance of the congestion between the anæsthetic patches four years after the leprosy began. Was this due to a fresh increase of bacilli in the mixed nerves, leading to invasion of the sympathetic fibers, and so to vasomotor disturbances in the sound skin? This theory seems to derive support from the discovery of bacilli in the median, which we know is a mixed nerve, and also in the superior cervical sympathetic ganglion. But the question naturally arises, Why is this condition not more frequent? for thickening associated with the presence of bacilli is common enough in the median and ulnar nerves in leprosy. I think that the involvement of the superior cervical ganglion in this case may explain the difference. The leniency of the congestion after prolonged hæmorrhage from the bowel was interesting. This may have been due to reflex contraction of cutaneous vessels set up by irritation of the ulcerated intestine, or it may have been the result of simple drain of blood from

the bowel. Be the explanation of the case what it may, the condition is unique in my experience of leprosy, and at once impressed me as presenting a remarkable resemblance to the condition described by Raynaud. Strictly speaking, it ought not, perhaps, to be included under the head of trophic lesions, but had the patient lived longer it is quite possible that gangrene might have occurred.

## 2. CHARCOT'S JOINT DISEASE.

In two lepers I have noticed a form of arthritis reminding me forcibly of that described by Charcot as occurring in locomotor ataxia, and called by him "tabetic arthritis." The cases are as follows:

*Case 2.*<sup>1</sup>—Gopi, Hindu, aged 30, was admitted to the Leper Asylum on September 10, 1883, with anæsthetic leprosy of thirteen years duration. He was demented, and, though not dangerous to himself or others, caused considerable annoyance to the other patients from his habit of continually talking and making a noise. On February 26, 1885, the left wrist was found to be much swollen. There was effusion of fluid, and the hand was flexed toward the radial side. Grating was felt in the joint, and the carpus could be dislocated on to the anterior surface of the radius. There was no pain on manipulation. The carpal bones appeared thickened, and the fingers were shriveled and contracted. There was no history of injury, and no other joints were similarly affected. He said this condition of the wrist came on soon after the onset of the leprosy.

On May 7 a cataract of the left eye was successfully removed without chloroform or cocaine, the cornea being apparently entirely anæsthetic.

On June 2 it was noted that he walked with a jerky movement, lifting his feet high from the ground. At a late date the wrist joint became still more swollen. An incision liberated a considerable quantity of glairy pus. After this the swelling subsided, the incision healed, and the joint became much smaller than before, though still larger than normal. Unfortunately, I was absent from the colony when this patient died some years later, and so I had not an opportunity of examining the joint and spinal cord.

*Case 3.*—Galalal, Hindu, aged 56, was admitted to the Leper Asylum on September 19, 1888, with anæsthetic leprosy of eight years' duration. On September 21 Dr. Pedro de Montbrun amputated the right leg for gangrene. The patient made a good recovery, the stump being healed in about a month. On June 8, 1892, the left hand was found to be very edematous, and there was a brawny swelling extending up the arm. Several superficial incisions were made but no pus was found.

June 10: The swelling is less. A deep incision near the thumb liberated blood and serum. June 17: The hand is still much swollen and swelling has appeared above the wrist. More incisions were made. June 24: A fluctuating swelling above the left wrist was incised. Blood and serum escaped. July 4: The superficial swelling is less, but there is grating in the joints and much effusion. July 22: The wrist is much swollen. It was punctured, but only blood escaped. July 25: An incision liberated pus and blood. July 27: An abscess has burst on the back of the wrist. The swelling is much less. September 2: The wrist has greatly increased in size again. On incising the inner side a jet of several ounces of foetid pus escaped. September 16: Another abscess has pointed at the inner side of the wrist. An incision released much thick pus. October 3: There is hardly any fluid in the joint, but the carpus can be dislocated. March 17, 1893: There is grating and dislocation of the wrist. The muscles of the hand are much wasted.

The points especially insisted on by Charcot as characterizing tabetic arthritis are: (1) Rapideffusion of fluid; (2) rapid destruction of the articular ends of bones; (3) absence of pain. Hutchinson doubts the nerve origin of Charcot's disease, and thinks that the changes are due to the anæsthetic condition of the joints in locomotor ataxia, which allows patients to use and move a rheumatically inflamed joint in a way in which no other inflamed joints are used. This argument of course applies *a fortiori* to anæsthetic leprosy, for the joints in this disease are often far more anæsthetic than in locomotor ataxia. In the two cases now under consideration another question arises: Were these patients the subjects of tabes in addition to leprosy? In the first subject there was certainly the jerky gait of

<sup>1</sup> Lancet, September 25, 1886, p. 581.

tabes, but this may have been merely due to leprous anæsthesia of the soles of the feet. In the second case the patient had but one leg, so his walking power could not be fairly tested; moreover neither of the spinal cords has been available for examination. The first patient died during my absence, and the second is still living. Clinically, both cases suggested strongly the arthritis of Charcot, for the effusion of fluid and destruction of the joint seemed too rapid for mere accident. It is true that in the second case the patient gave a confused history of a sprain while bathing, but there is so great a tendency in patients of this class to attribute every disease to some traumatic cause, that statements are naturally accepted with reserve. There are thus seen to be three possible theories as to the causation of the arthritis in these two cases: (1) That it was the result of some slight injury to anæsthetic joints; (2) that it was due to tabes dorsalis occurring in lepers; (3) that it resulted from leprous changes in the peripheral nerves supplying the joint or in the spinal cord, or in both. I think that the evidence, as far as it goes, is somewhat in favor of the last theory.

### 3. SYMMETRICAL BEDSORES.

In 2 cases of lepersy I have seen symmetrical bedsores in the center of the buttocks. These closely resemble those described by Charcot under the name of acute decubitus, as occurring in connection with disease of the nerve centers, but especially in cases of hemiplegia. They must of course be carefully distinguished from ordinary bedsores due to pressure and want of cleanliness.

The following are short summaries of the cases:

*Case 4.*—Charles Samuel, white, aged 36, born in Trinidad, was admitted to the Leper Asylum on August 11, 1859, with anæsthetic leprosy of six years' duration. Anæsthesia gradually increased until almost the whole body was involved. March 5, 1885: A large abscess on the left buttock was incised, and several drams of very foetid pus escaped. March 24: There are two small sinuses on the right buttock discharging thin, unhealthy pus. On October 25 herniotomy was performed for strangulated right inguinal hernia. In spite of the anæsthetic condition of his tissues he made an excellent recovery, and there was a firm cicatrix in twenty-one days. He died of mixed tubal and interstitial nephritis on February 1, 1887. There was still a sore on each buttock. The sciatic nerves were normal, but the median and ulnar nerves were undergoing atrophy.

This patient had been leprous for thirty-four years when he died and for thirty-two years when the sores on the buttocks formed. It is interesting to notice that these appeared within a few days of one another. The result of the herniotomy showed that there was good recuperative power in the tissues, so that there was a probability that the bedsores were due to cerebral changes. I have never yet found leprous changes in the brains or spinal cords examined by me, though Tschiriew has found degeneration in the anterior cornua and Chassiot says he has detected leprosy bacilli in the cord.<sup>1</sup>

*Case 5.*—N., Hindu, aged 65, was admitted to the Leper Asylum on March 17, 1893, with mixed leprosy, which she said had lasted one year, but, judging from the deformity of her fingers, it had been probably much longer. She had gangrene of the extremities and numerous ulcers on the body. She died on March 26, nine days after admission. At the autopsy symmetrical circular bedsores were found in the centers of the buttocks; the median nerves were thickened; the spleen was hypertrophied, but the rest of the viscera were normal.

In both these cases the position of the bedsores in the centers of the buttocks rendered it very unlikely that they were due to pressure.

<sup>1</sup> Monatschrift für Prakt. Dermat., Hamburg, 1887.

## 4. PERFORATING ULCERS.

I have been in some doubt as to whether perforating ulcers can be fairly included among the rarer trophic lesions of leprosy. When, however, it is remembered how rare they are in subjects who are not lepers, and also how many other lesions are more common in leprosy than these ulcers, I think they may be discussed in this paper without very much straining of a point. Perforating ulcers, as seen in leprosy, closely resemble the perforating ulcers described as occurring in locomotor ataxia, in syphilitic or other disease of the posterior tibial artery, or in peripheral neuritis. It usually begins over the ball of the great toe or over one of the metatarso-phalangeal articulations. The opening is often small, and surrounded by greatly thickened epidermis, but on passing a probe the point may be felt just under the skin of the dorsum of the foot. More rarely the ulcer occurs over the heel and burrows into the calcaneum. In some of the cases there has been intense pain, contrary to the general rule. I have tried various treatments for this condition. In some cases I have incised the ulcer freely and removed any loose bone there might be; in others I have stretched the great sciatic; while in some patients I have combined nerve stretching with incision of the ulcer. In several cases healing has progressed very rapidly after stretching of the sciatic. The cavity has rapidly filled with granulations, the discharge has greatly increased and became thicker and more healthy looking, and in a few days a thin white cicatrix has begun to advance over the surface of the granulations from the edge of the ulcer. The question of course arises as to how far these changes are the result of the rest in bed which is necessitated by the stretching of a large nerve like the sciatic. The changes have, however, often seemed too rapid and vigorous to be accounted for by mere rest. The immediate relief of pain has been most marked in some cases. The sciatic has always appeared normal when exposed. Horsley's theory of a shaking of the spinal centers as a result of the stretching of the sciatic would seem to explain the changes in these cases, for sometimes after stretching a nerve on one side of the body improved sensation is noticed on both sides. The shaking of the cord can easily be shown in the dead body by cutting an opening and exposing an inch or two of the lumbar cord and then stretching the sciatic forcibly. In one case, when stretching of the sciatic gave no relief, amputation of the leg had to be resorted to, and dissection of the limb after removal showed the posterior tibial nerve to be greatly swollen, the fibers being separated by gelatinous material. It is not to be wondered at that stretching of the sciatic was ineffectual with such an interruption in the conduction lower down.

Nerve stretching, though affording temporary relief in many cases, was on the whole found to be unsatisfactory. The ulcers had a tendency to break down when the patients began to walk about again, and the pain often recurred. I therefore devised another method of treatment.<sup>1</sup> A bistoury is passed through the ulcer from the sole of the foot and is brought out at a corresponding point on the dorsum. All the tissues are then divided straight forward, the bistoury emerging between the toes. The incision is stuffed with lint to arrest hæmorrhage and prevent immediate closure of the wound, which is thus made to granulate from the bottom. If the ulcer should happen to be near the inner or outer side of the foot, the knife can be brought out on either of these surfaces, as the case may be. Dead bone must, of course, be taken away, if any is found in the ulcer ready for removal. I have now operated in the above way on upward of 24 perforating ulcers with considerable success. The following case may be cited as an illustrative one:

*Case 6.*—Sibu, Hindu, aged 42, was admitted to the Leper Asylum on March 1, 1887, with anæsthetic leprosy of five years' duration. March 18, 1889: Perforating

<sup>1</sup> Brit. Med. Journal, Nov. 8, 1890, p. 1059.

ulcer of right side incised and fragments of bone removed. June 15: Probe passed through to dorsum and counter opening made. July 29: Bistoury passed through and all tissues slit up forward between toes and incision stuffed with lint. August 5: Granulating well; no pain; another sinus slit up. August 16: Loose necrosed head of bone removed; granulations healthy. August 21: Incision healing well from the bottom. On May 16, 1892, diffuse suppuration in the tissues of the left forearm set in. This was followed by gangrene of the parts about the elbow and he died on May 25.

At the necropsy next day the viscera were healthy. The left forearm and arm were burrowed by abscesses up to midway between the elbow and shoulder. In the right foot was a firm linear cicatrix, where the ulcer had been incised. The cicatrix was equally firm on dorsal and plantar surfaces.

In view of the fact that perforating ulcer is associated with change in the peripheral nerves in the main trunks or in the spinal cord, it is difficult to explain the success of this operation. The ulcer certainly recurs in some cases, but a second operation, combined with removal of bone if necessary, again affords relief. In cases of repeated recurrence stretching of the sciatic may well be performed in addition to the incision. The procedure is only a modification of the well-known surgical practice of laying open a sinus and stuffing it so that it may granulate from the bottom. Hæmorrhage is easily controlled, and the only case in which I had trouble was one where the patient meddled with the dressings soon after the operation.

Dr. W. S. Barnes, writing in the *British Guiana Medical Annual* for 1892, says that he has adopted the treatment in the Leper Asylum there, and that he finds it safe, easy, and sure.

##### 5. A CONDITION RESEMBLING AINHUM.

One of the best descriptions of ainhum is that given by Crombie, who defines it as hypertrophy of the skin of the little toe near the digito-plantar fold, and of the tissues surrounding its middle and distal phalanges, with an attempt at spontaneous amputation at or near the first interphalangeal articulation, and in most advanced cases a conversion of the bony structures of the phalanges into fibrous tissue. Ainhum occurs only in negroes and Hindus. Nine times out of ten it is confined to one or both little toes, but in 5 out of 50 of Silva Lima's cases it occurred in the fourth toe, while Cranford has described it in the great toe, and Eyles<sup>1</sup> has seen it in a finger. The last observer has studied the histology of the condition, and believes that it begins as a slight wound or crack in the digito-plantar fold caused by external and accidental circumstances. The fold being deep, favors the retention of foreign bodies, such as sand or grit. The irritation of these foreign bodies if continued for any length of time would lead to hyperplasia, and the fold itself is not only favorable to furrow formation, but determines the direction of the furrow. Simple hypertrophy is followed by hyperplasia, and the papillæ are pushed down and strangled. The epithelial cells are thus removed from the blood supply and undergo horny change. Pressure on the subjacent nervi vasorum sets up vascular changes, which in turn bring about epithelial changes in more distal areas, and the process thus advances anteriorly. This theory, though it may partly explain the condition when it occurs in the little toe, will hardly account satisfactorily for the constriction when it affects a finger or the great toe in which there is no deep digito-plantar fold. I believe that in ainhum there must be some peripheral neuritis in addition to the action of foreign bodies. The latter would naturally take effect more rapidly in tissues subject to nerve disturbance. In leprosy, for example, perforating ulcers are often set up by the patient treading with his anæsthetic foot on a sharp stone or piece of broken glass. It is very difficult to obtain anatomical proof of neuritis in ainhum, for the condition is not a fatal one, and patients are usually lost sight of after ampu-

<sup>1</sup> *Lancet*, Sept. 25, 1886, p. 576.

tation of the affected toe. I have never met with an account of a dissection of the nerves above the constriction after death. In 1889 Mr. Targett showed for me at the Pathological Society of London two fingers from anæsthetic lepers, showing constrictions remarkably like those of ainhum. The specimens are now in the College of Surgeons Museum. Since that time I have met with several similar examples occurring both in fingers and toes. The following are brief notes of 9 cases:

1. M. W., negro, aged 46; anæsthetic leprosy for eighteen years. The left middle finger is shortened from absorption of bone. The last phalanx is very small and placed on a broad base, composed of the first and the remains of the second phalanx. There is a constriction round the proximal end of the last phalanx, as if a piece of skin had been tied tightly round it. The last phalanx was removed with scissors. There was no bone at the constriction. The nail at the end of the finger was intact.

2. M., Hindu, aged 45; anæsthetic leprosy for fourteen years; left forefinger swollen; a sinus at the end leads to dead bone. There is a constriction round the swollen finger like that of ainhum. The finger was amputated. Three years later a similar constriction was found round another. Through an oversight my notes do not say at what parts of the fingers these constrictions were.

3. J. C., negro, aged 60; mixed leprosy for fourteen years. One of the smaller toes of the left foot shows a groove-like ainhum. The toe was amputated. No bone was found at the site of amputation. It was replaced by thickened fibrous tissue.

4. E. R., negro, aged 31; anæsthetic leprosy for six years. Over the last joints of the right middle finger is a commencing constriction like ainhum. The tip of the finger was amputated with scissors.

5. I. C., colored Spaniard, aged 47; anæsthetic leprosy for twenty years. The right fourth toe hangs by a narrow pedicle. It was amputated with scissors.

6. S. A., negro, aged 42; anæsthetic leprosy for nine years. The end of the right little finger is atrophied and there is a deep constriction separating it from the rest of the finger. It was amputated with scissors.

7. A., Hindu, aged 26; anæsthetic leprosy for nine years. Round the first phalanx of the left great toe is a marked constriction. Patient says the constriction began after the removal of bone from the plantar surface. The constriction now passes through the cicatrix. The end of the toe is slightly swollen. The nail is intact. The constriction went on deepening. Eventually both the toe and metatarsal bone had to be removed for necrosis. Five years later a deep constriction was discovered round the right fourth finger of the same patient at the base of the nail. This constriction also was attributed by the patient to removal of bone. There was much thickening of the bone just below the constriction.

8. M., Hindu, aged 54; anæsthetic leprosy for ten years. Round the end of the right middle finger is a deep constriction like ainhum. The bone has disappeared. The end of the finger was removed.

9. M. X., colored, aged 25, anæsthetic leprosy for six years. Round the great toe are two constrictions like ainhum. That near the distal end is ulcerated and bleeding. A sinus was slit up in the toe and a large piece of phalanx was removed. It was necrosed, loose in the cavity, and had a very offensive odor.

These nine cases have certain points in common. The leprosy had lasted a long time, there was much anæsthesia, and there was a constriction resembling that sometimes seen in the bark of a tree when the tree has gone on growing while some substance has been tied round it. In addition to this, there was in several of the cases either dead bone, or a cicatrix, showing that bone had been removed. No. 7, a patient of considerable intelligence, dated each of his two constrictions from the removal of bone. The sequence of events, I think, is very probably as follows: Peripheral neuritis causes anæsthesia and necrosis of bone. This dead bone acts as a foreign body, just as the grit or sand mentioned by Eyles in ainhum. Hyperplasia is thus set up with the consequent changes already described. A difference in leprosy is that constriction is not always limited to one toe and one part of the toe, but may occur almost indiscriminately in any finger or toe and over any joint or phalanx. It is probable that the transverse direction of the furrow is decided by pressure directed against the weakened end of the finger or toe after loss of bone. This seemed to be shown in case No. 7, in which the patient, having lost his other fingers, used to hold his spoon and other things between the thumb

and end of the fourth finger. It is conceivable that the movement backward and forward thus set up would soon increase the hyperplasia and other changes where the bone had been lost and thus produce a constriction. I think that further study and dissection of these leprous constrictions, combined with dissections, if possible, of the nerves in ainhum, will probably throw much light on the later obscure affection.

#### 6. OPHTHALMIC LESIONS.

A volume might be written on the affections of the eye occurring in leprosy, but space will only permit a very brief allusion to them. In tubercular leprosy various changes may take place from the deposit of tubercles in the conjunctiva. These changes, being associated with the presence of a distinct local growth, do not answer the present inquiry. In the other forms of leprosy more obscure lesions occur. Ophthalmia is the most frequent; it is complicated occasionally with pannus. Ulcer of the cornea is also by no means uncommon; it is sometimes followed by onyx, hypopyon, or other varieties of abscess, by perforation of the cornea, or by iritis with resulting synechia. In some cases the ulcer may heal under treatment, leaving usually some corneal opacity. In other instances, fortunately rare, panophthalmitis is set up, and the eye is rapidly lost. In all these conditions we are at once faced by the old difficulty as to the condition of the eye and face. We know that when the trigeminus of a rabbit is divided in the skull there is loss of sensation in the parts of the face receiving its sensory fibers. Within twenty-four hours the cornea becomes cloudy, and an inflammation follows which may end in total disorganization of the eye. At the same time the nasal cavities of the same side are inflamed and ulcers often occur on the lips and gums. Snellen, however, found that the inflammation of the eye might be greatly lessened or altogether prevented if the organ were carefully protected from the irritation of foreign bodies. Hence he argues that the changes are due to injuries produced by these foreign bodies on a surface no longer protected and guided by sensation. Other observers, on the other hand, have failed to obtain Snellen's results. In leprosy we have a condition closely resembling the effect of section of the trigeminus. The cornea is often more or less anæsthetic, sometimes absolutely so, as in case 2, in which I was able to extract a cataract without any artificial anæsthetic and without any evidence of pain or sensation on the part of the patient. The question therefore becomes the same as that already discussed in Charcot's joint disease, "Are the ophthalmic lesions the result of injuries to eyes rendered anæsthetic by leprous deposit in the sensory nerves, or are they caused by leprosy of distinct trophic fibers?" From the frequency with which these lesions yield more or less to local treatment, and also from the fact that in some instances they can be traced to the direct impact of foreign bodies, such as white-wash in the case of patients who clean the ceilings of the wards, it would seem that the former is the more probable hypothesis.

#### 7. ZONA.

I have observed zona seven times in lepers during a period of six years. When it is remembered that interstitial neuritis is the most common lesion in zona, it is somewhat surprising that the latter affection is not more common in leprosy. Radcliffe Crocker points out that the occurrence of cases in groups suggests the possibility of atmospheric influences as an existing cause of the disease. This almost epidemic occurrence of zona is sometimes noticeable in Trinidad both in lepers and those free from leprosy. In the asylum I have seen patients in adjoining beds attacked with zona one after the other, a fact which might be seized upon by unscientific observers to prove the contagiousness of zona, just as the fact of one patient after another becoming leprous has been brought forward to show

that leprosy is contagious. Amongst the general population of Trinidad it has occasionally happened that many persons have been attacked almost simultaneously with zona. Charcot specially mentions zona as occurring in the course of locomotor ataxia. Another is thus added to the many points of resemblance between the trophic lesions of tabes and leprosy.

These imperfect notes may perhaps help to emphasize the fact that some of the most interesting lesions in leprosy have their prototypes in diseases already described in Europe or elsewhere, and the complexity of many of the questions raised may serve to recall the Socratic dogma, that he is a wise man who learns that he knows nothing.

## THE QUESTION OF THE COMMUNICABILITY OF LEPROSY.

By BEAVEN RAKE, M. D., of London,

*Medical Superintendent of the Trinidad Leper Asylum, late Member of the Indian Leprosy Commission.*

From the earliest times leprosy has been regarded as communicable from one person to another. Under the Mosaic dispensation and in mediæval Europe there were stringent regulations providing for the segregation of those suffering from the disease. This ancient opinion as to the communicability or contagiousness of leprosy has not entirely held its ground in this century, and I propose to-day to briefly discuss some of the modern evidence for and against the theory of contagion. The subject may be conveniently considered under the following six heads: (1) Bacteriological evidence; (2) inoculations of animals; (3) inoculations in the human subject; (4) vaccination; (5) practical experience; (6) alleged increase of leprosy.

### 1. BACTERIOLOGICAL EVIDENCE.

To Hansen, of Bergen, is due the epoch-making discovery of the leprosy bacillus, and the inauguration of a new and scientific study of the disease. He first advocated the parasitic theory of leprosy in 1869. For some years, however, he was in much doubt on the subject. Writing in 1875,<sup>1</sup> he says:

There are to be found in every leprous tubercle, extirpated from a living individual, small staff-like bodies, much resembling bacteria, lying within their cells; not in all, but in many of them. Though unable to discover any difference between these bodies and true bacteria, I will not venture to declare them to be actually identical.

In 1880<sup>2</sup> he was able definitely to announce the discovery of a specific bacillus in leprosy, and Neisser,<sup>3</sup> in the autumn and winter of the same year, working at the San Lasaro Leper Hospital, at Granada, Spain, confirmed Hansen's results and applied the anilin-color tests, which have since been recognized as distinguishing the bacilli of leprosy and tuberculosis from those of other diseases. Neisser found bacilli in the cutaneous nodules, the mucous membrane of the mouth, palate, and larynx, the connective tissue of the peripheral nerves, in cartilage, and in the cornea, lymphatic glands, spleen, liver, and testicle. Since then Hansen's discovery has been confirmed by observers in all parts of the world, and it may now be affirmed that the leprosy bacillus is present in some part or parts of the body of every leper at some period or other in the course of the disease. Leprosy being thus associated with the constant presence of a microbe, which is

<sup>1</sup> Med.-Chi. Review, 1875, p. 489.

<sup>3</sup> Virchow's Archiv, 1881, Band 84, p. 514.

now believed, though not proved, to be the cause of the disease, there has been too great a tendency to assume that leprosy is therefore contagious. It is only necessary to mention malaria and pneumonia as two instances of infectious diseases which are by no means contagious.

It may now be well to examine the results which have attended the attempted cultivation of the bacillus lepræ. Hansen<sup>1</sup> kept specimens of leprosy blood in a moist chamber and obtained a mycelial growth, which at that time he called a leprosy culture. It is, however, probable that the growth was due to contamination of the specimen, and Hansen has since abandoned his original view. Neisser,<sup>2</sup> when working at Granada, removed an unbroken tubercle with every precaution, and finely divided it with needles sterilized in a flame. He then inoculated blood serum in hollow, ground, microscopic slides, in sterile test tubes, and under cover glasses in a space where evaporation was checked. All the preparations were kept at 35° to 39° C. He also kept pus and juice from a leprosy nodule in capillary glass tubes, which contained much air and were sealed. As a result of these cultivation experiments he describes three different bacilli. He failed, however, to cultivate any of them in generations, and it is therefore impossible to be certain that he got a true culture. Arning<sup>3</sup> allowed pieces of leprosy tissue to macerate and decay for several months in water at ordinary temperatures, and described growths of the leprosy bacillus, but he did not regard these as real cultivations.

At the Trinidad Leper Asylum<sup>4</sup> I made an extensive series of cultivation experiments extending over about three years. As nutrient media I used blood serum, ascitic fluid, hydrocele fluid, all from the bodies of lepers, and various combinations of agar and gelatine with these fluids. Pieces of cutaneous leprosy nodules, of lymphatic glands, and of nerves were used for inoculation, also fragments of the viscera of lepers and vaccine lymph. Numerous growths of staphylococci of various kinds were obtained, but no cultures of leprosy bacilli. Inoculations of animals with the growths were negative. Results obtained by allowing pieces of tubercle to putrefy in fluids were equally negative; nor did I observe the abundance of leprosy bacilli described by Arning in the earth in which lepers had been buried. To test this point, I buried leprosy hands and other specimens and dug them up at varying intervals. Examinations of the surrounding earth failed to show any specific bacilli.

Delépine and Slater<sup>5</sup> made numerous attempts to cultivate the leprosy bacillus at two different periods during the life of a leper, but without success. In 1887 Bordoin Uffreduzzi,<sup>6</sup> of Tunis, announced the cultivation of the bacillus lepræ. Having failed, like other experimenters, to grow the bacillus from pieces of leprosy nodules implanted in solid media, he considered that the bacilli in these nodules are inclosed in cells and are probably dead. He therefore examined other tissues, and in the bone marrow of a dead leper he found free bacilli. He inoculated tubes of peptone-glycerin-serum with fragments of this bone marrow and obtained cultures of a small bacillus, frequently bulbous at the ends and resembling in form and size the bacillus of the tissues. It, however, took the fuchsin stain with far more difficulty than the bacillus found in the tissues of lepers.

When passing through Tunis, in 1891, I called on Prof. Bordoin Uffreduzzi, who very courteously showed me microscopic specimens from his original culture, and gave me a tube of one of the secondary cultures. I took this tube to London with all possible care, and inoculated other tubes from it in Dr. Slater's laboratory,

<sup>6</sup> Zeitschrift für Hygiene, Band III, p. 178.

which he kindly placed at my disposal. I fear, however, some contamination must have taken place, for the subcultures which I grew differed entirely from the growth originally figured by Uffreduzzi. It may be stated here that the Italian professor made a large number of inoculation experiments on animals, but wholly failed to establish the pathogenic nature of his cultivation. Gianturco,<sup>1</sup> at Naples, has succeeded in obtaining a cultivation which Uffreduzzi considers identical with his own. More recently Campana,<sup>2</sup> at Genoa, has described a third bacillus as cultivated from leprous material. I have seen specimens from the cultures of Gianturco and Campana, but could not feel convinced that they were leprosy bacilli.

A series of culture experiments were carried out at Almora and Simla by Dr. Buckmaster, Surg. Maj. Thomson, and myself.<sup>3</sup> The mode of procedure was suggested by Dr. Buckmaster. Blisters were raised over cutaneous leprous nodules, and at the same time over areas of normal skin in lepers. Sterilized capillary vaccine tubes were then charged with a minute quantity of the fluid from the blister over the tubercle, and with seven or eight times as much fluid from the blister over the normal skin. The tubes were then sealed in a flame. In order to secure a constant temperature the tubes were packed with a small thermometer in a cylindrical box and carried in the axilla. After incubation for one month the tubes were opened, examined, and resealed. Several bacilli resembling that of leprosy were seen. A tube containing some of these bacilli was now sterilized as much as was possible without injury to the contents, broken at both ends, dropped into glycerin bouillon, and shaken. On the third day a slight turbidity appeared and increased daily. Minute particles collected on the surface, and, adhering together, formed a pellicle, which gradually extended from the center to the periphery. From this original bouillon glycerin, gelatine and glycerin-agar were inoculated and vigorous growths were obtained. Similar results were obtained from two different patients. Under the microscope these growths showed thick clusters of bacilli shorter and slightly thicker than the bacilli found in leprous nodules, but retaining the pink stain after treatment in warm Ziehl's solution for twenty minutes, and subsequent decolorization in 25 per cent solution of nitric acid. Subcultures from the original growths did not resist the action of the acid so well, though they stained to some extent. Rabbits, dogs, and a monkey were inoculated with small quantities of these cultures, but the results were entirely negative. We are thus unable to assert positively that the growths obtained were those of the bacillus lepræ, but that the bacillus cultivated by us had several points in common with that in the tissues is undoubted.

In concluding this section I may be pardoned for quoting the four well-known postulates which have been laid down by Koch, as necessary to show beyond a doubt that a micro-organism is the cause of a disease: (1) The micro-organism must be found in the blood, lymph, or diseased tissues of the man or other animal suffering from or dead of the disease. (2) The micro-organism must be isolated from the blood, lymph, or tissues and cultivated in suitable media outside the body. These pure cultivations must be carried on through successive generations of the organism. (3) A pure cultivation thus obtained must, when introduced into the body of a healthy animal, produce the disease in question. (4) In the inoculated animal the same micro-organism must again be found. Applying these postulates to the case of leprosy it will be evident, from the experiments of the various observers whom I have quoted, that the first is generally admitted, the second is doubtful, and the third and fourth have never yet been demonstrated.

## 2. INOCULATION OF ANIMALS.

These may be of two kinds: (1) Inoculations with cultures. (2) Inoculations with tubercles or other pieces of leprous tissue. We can not logically speak of inoculations with cultures of the bacillus lepræ, for as was shown in the last section, such a culture has not yet been demonstrated beyond possible doubt. All we can say is that cultures of bacilli obtained after inoculation of media with leprous products have always failed to produce leprosy in animals. This has already been alluded to in the last section. The other method of inoculation of animals which has been tried is by means of pieces of leprous nodule or other leprous tissue. Neisser<sup>1</sup> was one of the first to inoculate animals with leprous tissue. When working at Granada in 1880, as already mentioned, he experimented on rabbits and dogs. Pieces of freshly extirpated leprous tubercle were introduced into the peritoneal cavity and anterior chamber of the eye of rabbits. The results in them were absolutely negative. Pieces of leprous tubercle were also placed beneath the skin of dogs. One of them died after a month, and a small nodule was found at the site of inoculation. This contained numerous bacilli. Another dog was killed about three months after inoculation, and a local nodule the size of a bean was found. This contained characteristic leprous cells, but no bacilli. Neisser was of opinion that a local leprosy was thus produced, which, however, did not become general. Damsch<sup>2</sup> introduced leprous tubercle into the anterior chamber of the eye of rabbits, and described an infiltration of the iris, ciliary body, and Descemet's membrane with cells containing leprosy bacilli. Vossius<sup>3</sup> obtained similar results, but neither of these observers found a distribution of bacilli through the body. Wesener, Leloir, and Campana<sup>4</sup> have shown that results identical with those described by Damsch and Vossius are obtained on implanting leprous material hardened for years in alcohol. Dead leprous bacilli even after having been so kept in alcohol retain their structure, shape, and staining reaction. It is therefore extremely probable that Damsch and Vossius did not produce a local leprous lesion. Campana<sup>5</sup> inoculated leprous tubercle in the vascular comb and beard of fowls, and often obtained at the site of inoculation a local tumor containing large cells produced in the inflammatory process. These took up leprosy bacilli in the same way as leucocytes take up inorganic foreign bodies. Köbner<sup>6</sup> and Hansen<sup>7</sup> obtained negative results in monkeys after inoculation. Hillairet and Gancher<sup>8</sup> inoculated a pig with leprous tubercle, but the results were negative. Vidal<sup>9</sup> also performed a similar experiment, and sections of the skin and subcutaneous tissue containing the inserted fragment showed a year after the inoculation numbers of leprosy bacilli in the implanted mass, but none in the surrounding tissue. Thia,<sup>10</sup> Kauria,<sup>11</sup> Avuing,<sup>12</sup> and Leloir<sup>13</sup> have hitherto failed to establish leprosy in animals.

At the Trinidad Leper Asylum<sup>14</sup> I have made a series of experiments extending over nine years. The animals used have been cats, pigs, rabbits, bats, guinea pigs, fowls, small birds, a parrot, and a dog. The materials employed have been

pieces of cutaneous nodule, discharge from ulcers, and vaccine lymph. There has been no evidence of success. In fowls the inserted nodule becomes encysted beneath the skin and then becomes disorganized. Dead bacilli can be found in the débris many months after inoculation. Bacilli have, however, never been found in any of the viscera. I fed fowls for long periods with pieces of cutaneous leprous nodule and enlarged glands and pieces of viscera obtained post-mortem, but dissection of these fowls after death failed to show any evidence of leprosy. I have now under observation two pigs, which were inoculated with pieces of cutaneous leprous nodule nearly four years ago. There is nothing to be seen or felt at the site of inoculation. In the last year these pigs have been fed with large masses of viscera and enlarged and caseating glands, obtained from the bodies of lepers. Up to the present they have seemed in fair health.

The experiments which have attracted most attention of late years are those of Melchor<sup>1</sup> and Ortmann<sup>2</sup> in Königsberg. They introduced pieces of freshly extirpated leprous tubercle into the anterior chamber of the eyes of rabbits, and described four months afterwards a visceral and lymphatic gland lepræ. The autopsies showed the cæcum, spleen, lungs, and lymphatic glands to be infiltrated with nodules varying in size from that of a pin's head to that of a pea. In these nodules were quantities of bacilli which they regarded as those of leprosy. Arning<sup>3</sup> and Ruffer, who have examined the specimens of Melchor and Ortmann, are convinced that the Königsberg experiments have succeeded in inoculating animals with leprosy. Wesener, on the other hand, has carefully gone over the same ground and critically controlled these experiments, and he concludes that proliferation of the leprosy bacilli does not occur, but merely a diffusion of the bacilli introduced. He and Hüppe believe that Melchor and Ortmann, like many others, have sown leprosy and reaped tuberculosis.

In this connection, I may allude to a series of observations at the Trinidad Leper Asylum, some of which I have recently published.<sup>4</sup> In a large proportion of the bodies of lepers, I have found either (1) pulmonary phthisis indistinguishable from that occurring in nonlepers, and characterized by small tubercles scattered more or less throughout the lungs, and often agglomerating, caseating, and breaking down into large cavities at the apices and elsewhere; or (2) a general diffusion of small gray or yellow tubercles throughout the viscera, and sometimes on the serous membranes. The latter condition often appears at the autopsy to be of very recent date, and from the clinical symptoms, such as fever and wasting, which come on a few weeks before death, it would seem that the appearance of these visceral tubercles coincides with the absorption of cutaneous leprous nodules which so often precedes death. We are therefore led to the conclusion that these visceral tubercles are either leprous, and due to absorption of leprous products from the skin, or they are tuberculous, and due to accidental absorption of tuberculous material quite apart from the leprosy.

I inoculated five guinea pigs beneath the nape of the neck with small pieces of pulmonary tubercle taken from three different lepers. The five guinea pigs died or were killed at periods varying from four to six months after inoculation, and in all of them were found enlargement and caseation of lymphatic glands, and small nodules in the lungs, and sometimes in the liver or spleen, or both, varying in shape, and in size ranging from about one-sixteenth to one-third of an inch in diameter. In the lungs they were translucent, and in the spleen and liver yellow or dark red in color. Microscopic examination showed bacilli indistinguishable from tubercle bacilli. As I have frequently inoculated guinea pigs with leprous cuta-

<sup>1</sup> Berl. Klin. Wochenschrift, 1885, No. 13.

<sup>2</sup> *Ibid.*, 1886, No. 9.

<sup>3</sup> Journ. of Lepr. Investig. Committee, No. 2, p. 117.

<sup>4</sup> Lancet, April 1, 1893, p. 719.

neous nodules and have always found no change whatever in the viscera after death, I am led to conclude that the above-described nodules are tuberculous in nature, and further, that they are derived from the pulmonary tubercles of lepers. If they were derived from material introduced accidentally during the process of inoculation, we should expect equally to find them following the inoculation of leprosy material. This is what Wesener claims for Melchor and Ortmann's inoculations, but in my experiments, as already stated, I have never found such nodules. The obvious inference, then, is that the visceral tuberculosis so common in lepers is tuberculous, i. e., connected with the presence of the bacillus tuberculosis. But if this visceral tuberculosis is due to absorption of cutaneous leprosy tubercles we are faced by a new difficulty, to which there are only two solutions: (1) There is absorption of independent tuberculous material, presumably tubercle bacilli, through the open ulcers so common in leprosy tubercles. (2) The bacillus lepræ and the bacillus tuberculosis are varieties of the same bacillus, as suggested by Danielssen.<sup>1</sup> It is obvious that the question is by no means solved yet, but these recent experiments of mine have an important bearing on Melchor's and Ortmann's results and Wesener's criticism. I may state here that I failed to obtain cultures of either bacillus lepræ or bacillus tuberculosis from the original nodules in the lungs of the lepers, or from the nodules produced in the viscera of the guinea pigs after inoculation. From a consideration of all the evidence given in this section we are, I think, driven to believe with Besnier that leprosy is an essentially human disease and can not be transmitted to animals.

### 3. INOCULATIONS IN THE HUMAN SUBJECT.

Intentional inoculations performed on man have necessarily been few. Like those on animals, they may be of two kinds: (1) Inoculations with microorganisms obtained in attempted cultures of leprosy bacilli. (2) Inoculations with pieces of tubercle or other leprosy products.

*Inoculations of culture products.*—Healthy subjects for inoculation not being obtainable, I determined to try the effect of inoculation of culture products in anæsthetic lepers. During the latter half of 1889 I made some cultures on agar and serum and on solidified hydrocele fluid from a fragment of cutaneous leprosy nodule and from a piece of liver from the body of a tuberculated leper. The microscope showed this liver to contain numerous leprosy bacilli. The growths obtained from these tissues showed no leprosy bacilli, but quantities of micrococci. Though these cultures were thus negative in not containing the specific organisms of leprosy, I thought it worth while to try the effect of injecting them, for it was quite possible they might contain other products not recognizable by the microscope. I may remark in passing that these experiments were made a year before Koch brought tuberculin before the world, and an account of them has been published.<sup>2</sup>

I chose 12 anæsthetic lepers and injected solutions of the growths above mentioned beneath the skin in various parts of the body. The immediate result was in most cases local swelling, redness, and tenderness, with more or less temporary rise of temperature. These symptoms usually passed off in a few days. In one or two cases, however, an abscess formed at the site of injection. The later history of the cases was as follows: Four of the patients died within the next two years of intercurrent disease. No development of tubercles was found in them, either locally or elsewhere. The eight survivors were examined by me on May 29, 1893, nearly four

<sup>1</sup> Archiv. Roum. de Méd. et Chir., January, 1889, p. 16.

<sup>2</sup> Report of Trin. Lep. Asyl., 1889; Brit. Med. Jour., January 3, 1891, p. 12.

years after inoculation. In six of them there was no thickening or any indication of the site of inoculation, and no tubercles had developed anywhere. In the two remaining patients there were in one case a thick crop of tubercles, and in the other a diffuse infiltration of the skin, together with tubercular masses on the face and ears. The following are short summaries of the cases.

*Case 1.*—A., Hindu, aged 38, was admitted to the Trinidad Leper Asylum on December 31, 1885, with anæsthetic leprosy of one year's duration. There were pale anæsthetic patches on the front and back of the trunk. The hands and feet were anæsthetic and the toes were ulcerated. On December 6, 1886, the left great toe was amputated. On August 29, 1887, it was noted that his condition was about the same as on admission. On December 16, 1887, a fragment of cutaneous nodule from R. G., another patient, was introduced beneath the skin of the back of the left forearm. The incision was closed with one silk suture. On December 24 there was a long ragged ulcer with thickening round it. On March 11, 1889, there was a cicatrix at the site of inoculation, but no thickening and no tuberculation. On October 16, 1889, about 10 minims of a solution of some of the growth from the liver of E. C., a tuberculated leper, was injected into the back of the right forearm with a hypodermic syringe. The puncture was protected from the air. On October 18 there was redness, hardness, and tenderness over an area of about three-fourths of an inch radius from the point of inoculation. On October 23 an abscess about 1 inch in diameter had formed at the site of inoculation. It was incised and found to contain thick yellow pus. On July 28, 1890, there was no change in the patient's general condition. After this I was absent from the colony for a year and eight months, and on June 20, 1892, about six weeks after my return, I found that the patient's face and ears were tuberculated. The dispenser told me they had been so for more than a year. The tuberculation has since increased, and the following notes were taken on May 29, 1893: There is general infiltration of the skin, especially on the trunk, upper extremities, and face; there are large masses of tubercle on the face and ears; on the back of each forearm is a depressed cicatrix, indicating the site of inoculation; the skin is raised and thickened round; the fingers are enlarged and tuberculated. As I was absent from the colony when these changes began, I am unable to say whether the infiltration started from either of the sites of inoculation.

*Case 2.*—K., Hindu, aged 35, was admitted to the Trinidad Leper Asylum on February 20, 1889, with anæsthetic leprosy of five years' duration. There were pale anæsthetic patches over the greater part of the trunk, face, and extremities. Some of the fingers and toes were missing, and the remaining ones were ankylosed, distorted, and anæsthetic. There was no trace of tuberculation anywhere. On October 16, 1889, about 10 minims of a solution of the same growth as in the last case was injected into the right temple. On October 18 there was a small tender nodule at the site of injection about the size of a pea, with some swelling round the eye. On October 23 there was no trace of the inoculation. On April 13, 1890, there was swelling of the face and a painful nodule above the left eye. The left hand was also swollen. On October 28, 1892, I found numerous small tubercles on the nose and forehead, varying in size from that of a small shot to that of a pea. The ears were thickened and tuberculated. There were also many tubercles on the hands and feet. There was no thickening or tuberculation in the right temple at the site of injection. On May 24, 1893, it was noted that there was tuberculation of the face, ears, and hands. These parts were invaded by many small discrete tubercles. There were also a few on the front and back of the chest.

In these two cases an eruption of tubercles occurred some time after the injection in anæsthetic lepers of products derived from the attempted culture of leprosy bacilli. Whether these eruptions were *propter hoc* as well as *post hoc* is a difficult question. There are two possible fallacies: (1) The anæsthetic lepers might have developed tubercles independently of any injection. I have never seen a purely anæsthetic leper develop tubercles, but Leloir<sup>1</sup> quotes three cases; so we must admit the possibility. (2) The injection of an irritant such as the micrococcus may, through the febrile disturbance thus set up, have liberated bacilli already present in the peripheral nerves, and these by their entry into the lymphatics of the skin and subcutaneous tissue may have brought about tuberculation. It is evident that experiments made on subjects already leprous can only have a partial value, but

<sup>1</sup> *Op. cit.*, p. 209.

in view of the extremely rare occurrence of tuberculation in an anæsthetic leper the trial seemed worth making. Though no leprosy bacilli were present in the cultures, it is quite possible that some ill-defined product, such as an albumose, may have been there and may have produced the leprosis.

*Inoculation of leprous tubercle or other products.*—The classical example of inoculation of a healthy man with leprous tubercle is the inoculation by Dr. Arning<sup>1</sup> of the Hawaiian convict Kenau in the Oahu jail on September 30, 1884. The case is so well known that I need refer to it only very briefly. A small piece of leprous nodule was introduced beneath the skin of the left forearm, and a month later the patient suffered from pains in the left shoulder, elbow, and wrist, accompanied by painful swelling of the ulnar and median nerves. There was no fever and only very slight constitutional disturbance. During the next six months the neuritis gradually decreased and a small leprous nodule formed where the inoculation took place. Leprosy bacilli could be detected here sixteen months after the inoculation. In September, 1887, distinct symptoms of leprosy developed, and a year later the disease was fully established. Though at the time Dr. Arning made the experiment he was assured by Kenau himself and by those who knew him that his family was free from leprosy, yet it afterwards came out<sup>2</sup> that his son, nephew, and maternal first cousin were lepers, either before or after the date of the inoculation. It would thus appear that in addition to the strong racial predisposition to leprosy which exists in Hawaiians, there was in Kenau's family a peculiar aptitude for taking the disease. It is therefore quite possible that he may have had latent leprosy when he was inoculated. Moreover, as Arning points out, we have at present no criterion of the living leprosy bacillus, and it is therefore quite possible that the bacilli in the inoculated nodule may have been dead at the time of the experiment. From whatever point we look at it, we can by no means regard this inoculation as conclusive, and Arning himself freely admits that it is not a crucial test.

Nearly forty years ago a Norwegian physician<sup>3</sup> inoculated himself and 20 healthy individuals with blood, fragments of cutaneous nodules, or with blood or pus from such nodules. All those who were inoculated were watched for many years, but all remained healthy. Profeta<sup>4</sup> inoculated himself and 9 other healthy people. The observations extended over a period of sixteen years, and were absolutely negative. The materials used were pus from leprous ulcers and blood from tubercles and from anæsthetic patches. These were rubbed into the scarified skin or into raw surfaces produced by blisters or injected beneath the skin by means of a Pravaz syringe. Similar experiments have also been made by Danielssen, Holst, and Titsch,<sup>5</sup> all with negative result. Hansen<sup>6</sup> inoculated anæsthetic lepers with material obtained from tuberculated lepers, but no development of nodules took place.

In the Trinidad Leper Asylum I inoculated 30 anæsthetic lepers in December, 1887, and January, 1888, with fragments of cutaneous leprous nodules.<sup>7</sup> In 1889 3 more anæsthetic lepers were inoculated with pieces of nodule taken during acute leprosis (i. e., fever accompanied by an outbreak of tubercles). I thought that possibly during these acute attacks the cutaneous nodules might contain living bacilli, and thus their inoculation might be followed by a development of the disease. Since the inoculations were performed 9 of the patients

<sup>6</sup> Leloir, *op. cit.*, p. 238.

<sup>7</sup> Berlin, Klin. Wochensch., January, 1891, p. 25.

have died and 1 has left the asylum. In none of them was any development of tubercles noted. The remaining 23 were examined on May 29, 1893. Twenty-two of them were then absolutely free from tubercles, though in 1 there had been, three months after inoculation, a subcutaneous nodule to the outer side of the cicatrix about the size of a small shot. This, however, had disappeared in another month. The twenty-third is the patient already described under case 1 as having been also injected with culture products. It is, therefore, evident that we can not say whether he became tuberculated as a result of the leprous nodule inoculation, of the culture injection, of both of these, or independently of them.

Putting all the inoculations together we find that out of a total of 40 anæsthetic lepers inoculated with either tubercles or cultures, or both, two developed tubercles afterwards, but it is impossible to say if this was the result of the inoculation. Thus the evidence hitherto obtained from experiments performed on man may be regarded as almost entirely negative, no case being beyond the possibility of doubt.

#### 4. VACCINATION.

Of late years the anti-vaccination party, after exhausting every other argument against vaccination, has endeavored to show that leprosy is often spread in this way. Probably the case which is most often quoted is that published by Gairdner<sup>1</sup> in 1887. A doctor in a tropical island vaccinated his own child from a native child who afterwards became leprosy. Another white child was vaccinated from the doctor's child, and both these children also developed leprosy. Though Prof. Gairdner carefully avoided expressing any opinion, and merely gave a statement of such facts as were known to him, the case was at once seized upon by those anxious to prove the communicability of leprosy by vaccination. A perusal of the case, however, shows that the details are very few, and insufficient to establish any conclusion. Moreover, leprosy was endemic in the island, so that the possibility of deriving it from outside sources was always present. Daubler<sup>2</sup> two years later published an account of two women on Robben Island, Cape of Good Hope, both of whom he believed contracted leprosy through vaccination. They were vaccinated with lymph obtained from a patient who afterwards died of tuberculated leprosy. In the first patient the site of inoculation swelled a few days after the puncture and became brown, but no true vaccine vesicle formed. After the swelling had subsided fever and rigors occurred, and by the eighteenth week there was a discolored tumefaction of the right frontal eminence. The second patient two months after the vaccination showed the typical leonine aspect of a tuberculated leper. These cases are frequently quoted, but clinical experience does not warrant the belief that such a chronic disease as leprosy is produced so soon after inoculation. More recently a long series of cases by Dr. Roger Chew, of Calcutta, has been published. In these cases, also, an attempt was made to show that leprosy was communicated by vaccination from diseased to healthy persons. The details, however, are very scanty, and the cases are open to the same objection which obtains in those already quoted. In Bengal there are districts where the percentage of lepers is as high as or higher than in any other part of India, though, as will readily be seen by a reference to the annual reports on sanitary measures in India, Bengal is by no means the most vaccinated province.

The proposition may be stated as follows: If vaccine lymph be taken from a child in a locality where leprosy is endemic, and if such lymph be sent to a country free from leprosy, and a healthy child in such country and who had never quitted the country, be vaccinated with such lymph, and if this child after vaccination and without leaving the country, develop leprosy, then it may be taken as proved that

<sup>1</sup> Brit. Med. Journ., June 11, 1887, p. 1269.

<sup>2</sup> Monat. für Prakt. Dermat., Band VIII, 1889, p. 123.

leprosy is communicable by vaccination. Probably this experiment has never been tried, for residents in Great Britain or other non-leprous countries would not be likely to send to the tropics for lymph. An experiment somewhat approaching the hypothetical one mentioned above has, however, been performed in India. Surg. Maj. Pringle<sup>1</sup> says that during a period of twenty years, from 1864 to 1884, when sanitary commissioner in the northwest provinces, he was in the habit of bringing vaccine lymph down from British Garhwal, a markedly leprous district, and using it for vaccinating in the plains between the rivers Ganges and Jumna. The first census return—1867 to 1872—shows that whereas the proportion of lepers in British Garhwal was 20 to 30 per 10,000, that in the plains between these two rivers it was only 1 to 5 per 10,000, with the exception of Etah, which showed 5 to 10 per 10,000. Here, then, we have an approach to a scientific experiment. Children in a district where leprosy is comparatively rare are vaccinated with lymph from another district where the disease is many times more common. If, then, vaccination is responsible for spreading leprosy we should expect an increase of the disease in this particular district. As a matter of fact, however, on comparing the first two census returns for the districts in question we find the following statement:

| Years.            | British Garhwal.         | District between Ganges and Jumna.                            |
|-------------------|--------------------------|---------------------------------------------------------------|
| 1867 to 1872..... | 20 to 30 per 10,000..... | 1 to 5 per 10,000, except Etah, which has 5 to 10 per 10,000. |
| 1881.....         | 10 to 20 per 10,000..... | 1 to 5 per 10,000, including Etah.                            |

Thus not only has leprosy fallen in British Garhwal from 20 to 30 per 10,000 to 10 to 20 per 10,000, but in the district vaccinated with lymph from British Garhwal the proportion of lepers has remained stationary, with the exception of Etah, which shows a reduction from 5 to 10 per 10,000 to 1 to 5 per 10,000. As Dr. Pringle was on duty from 1864 to 1884, and the number of individuals vaccinated with the lymph under consideration was gradually accumulating all these years, making due allowance for removal by death and other counteracting influences such as the diminution of leprosy in British Garhwal, we should expect that by 1881 the figures would show some evidence of the increase of leprosy which is alleged to follow the use of lymph collected in leprous districts. This increase, however, does not appear in the census returns.

It will be well to examine now the various direct experiments which bear on the subject of vaccination and leprosy. Arning<sup>2</sup> in Hawaii vaccinated three lepers and examined the vesicles. He found bacilli in the lymph and crusts in a case of extensive tuberculated leprosy, in which the skin contained bacilli. In two cases of pure anæsthetic leprosy he found no bacilli. In the Trinidad Leper Asylum<sup>3</sup> I made twenty-seven examinations of pure and impure vaccine lymph from vesicles raised in tuberculated, anæsthetic, and mixed lepers. Ehrlich's method of staining failed to show leprosy bacilli in any of the specimens, and animals vaccinated with lymph from lepers did not develop leprosy. I also vaccinated an anæsthetic leper with lymph from a mixed leper. Typical vesicles rose and ran the ordinary course, but there has been no development of tubercles. This experiment was done seven years ago. Dr. Simpson vaccinated some lepers in Calcutta, and stated that he found bacilli in the vaccine lymph. Unfortunately

<sup>1</sup> Leprosy and Vaccination, Brit. Med. Assoc., Bournemouth, July, 1891.

<sup>2</sup> Report on Leprosy in Hawaii, 1886, p. 45.

<sup>3</sup> Brit. Med. Journ., Aug. 20, 1887, p. 433.

when I was in Calcutta my time was so short that Dr. Simpson and I missed one another, though we attempted to meet. I thus lost an opportunity of seeing his specimens. At the Almora Leper Asylum<sup>1</sup> unusual facilities were offered, through the kindness of the authorities, for making an exhaustive study of vaccine lymph from lepers. Accordingly, Dr. Buckmaster, Surg. Maj. Thomson, and I caused all the available lepers to be vaccinated. Eighty-seven were vaccinated, and 40, 21 males and 19 females, developed vesicles which were examined. Of the 40 cases 34 were anæsthetic, 5 were mixed, and 1 was tuberculated. The condition of the skin at the point of vaccination was as follows: In 14 cases it was normal, in 13 cases there was an anæsthetic patch, in 12 cases sensation was diminished, and in 1 case there was tuberculation. The condition of the vesicle was as follows: In 31 cases normal, in 2 cases purulent, in 2 cases purulent and mixed with blood, in 1 case normal on one arm and purulent on the other, in 1 case normal but mixed with blood in taking, in 1 case immature, in 1 case immature and mixed with blood in taking, and in 1 case immature and the crust taken. Crusts were also taken from two vesicles which had been normal. Ninety-three cover glasses were prepared, and in no case were leprosy bacilli undoubtedly found. Suspicious looking rods taking fuchsin were seen in one case in vesicles raised over tuberculated ears, and in another case in vesicles over anæsthetic patches. But even if we were to consider these cases positive, and give them their utmost value, they would have little or no bearing on the question at issue, for no vaccinator would be likely to vaccinate a leper over a tubercle or anæsthetic patch and use the lymph obtained from such vesicle for vaccinating healthy individuals. Assuming the presence of bacilli to be necessary to produce leprosy, this series of observations, the most extensive yet made, goes to show that no danger need be apprehended from the vaccine lymph of even an actual leper, provided he is vaccinated on apparently normal skin.

From a consideration of the various arguments brought forward in this section we may therefore conclude that there is no danger of transmitting leprosy by using as a vaccinifer a child born of a family in which leprosy exists.

##### 5. PRACTICAL EXPERIENCE.

Almost all the alleged instances of communication of leprosy from one person to another have occurred in countries where the disease is endemic, and are therefore open to the objection already referred to under previous headings, viz., that the leprosy may have been derived from outside sources. As an impartial observer I may record the following case which has come under my notice during the past year. It is a typical example of the histories so often quoted, but it has the additional merit that to a great extent I was able independently to verify the dates:

J. R., negro, aged 49, consulted me at Diego Martin on July 5, 1892, for a perforating ulcer of the foot. On examining him further I discovered anæsthesia of the upper extremities, and decided that he was an anæsthetic leper. He then told me that five years ago he was living for six months at Cocorite with M. A. T., a notoriously bad character, who had previously been discharged from the leper asylum for misconduct. At that time he said he was healthy. About two years after he left the woman ulcers formed on his feet, and he lost sensation in his hands. At that time I had entirely forgotten that I had ever seen the man before, but some months later when I was looking through the register of our patients for other purposes I happened to come upon his name under date of July 21, 1890. He was entered in the register as a doubtful case of leprosy and as living at Mucurapo. Thus an unexpected corroboration was afforded of the patient's statement as to dates, for at that time, according to what he told me, he must have had initial symptoms for about six months, and it is evident that they were not sufficiently clear to justify more than a doubtful diagnosis.

<sup>1</sup> Journ. of Lepr. Investig. Com. No. 4, Dec., 1891, p. 32.

During our investigations in India we were brought in contact with many cases of supposed contagion of leprosy. As will be seen on reference to the Report of the Leprosy Commission<sup>1</sup> all these cases broke down on examination, with the exception of that of a sweeper at the Calicut Leper Asylum, who had been employed in dressing the ulcers of the inmates for twenty-three years. Two years before our visit he had developed leprosy. Even in this case there was a discrepancy as to dates, an old inmate of the asylum asserting that the sweeper had suffered from leprosy for at least six years, but that he was apparently healthy twenty years ago. The extreme difficulty in getting any coherent statement as to dates from an Oriental is, however, so well known that we must concede to this case whatever value it possesses. The dates given by the two men are fairly approximate. The death of Father Damian from leprosy is familiar to all, but here again we have no evidence that he contracted the disease from a leper. Leprosy is so prevalent in the Sandwich Islands that it is quite possible that he may have derived it from outside sources.

The only case which is free from the fallacy of concomitant variations already mentioned is that reported by Dr. Hawky Benson,<sup>2</sup> of Dublin. A man, after twenty-two years' service in India, returned to Ireland with fully developed leprosy. He was shown by Dr. Benson at a meeting of the Dublin Medical Society in 1872. He died a year and a half later. During this last period of his life his brother slept in the same bed with him and wore his clothes. This brother, who had never been out of the United Kingdom, developed leprosy almost three years after the death of the first patient, and was shown by Dr. Benson at a meeting of the Dublin Medical Society in 1877. It is much to be regretted that photographs of the two brothers were not taken, but I am informed on good authority that there were present at the meetings of the society doctors who had been abroad and seen leprosy, and who were therefore capable of confirming the diagnosis.

Cases of the occurrence of leprosy in persons living in a leprosy-free country, and who had never quitted it, are also reported by Dr. Edmund Atkinson,<sup>3</sup> in Maryland, and by Dr. Rees,<sup>4</sup> in Stepney. In neither of these cases, however, was actual contact with a leper established, though in Dr. Atkinson's case there was a strong suspicion of such contact. In discussing any case occurring in a country free from endemic leprosy it must also be borne in mind that the diagnosis between leprosy and syphilis, especially in their early stages, is often extremely difficult, so that mistakes may quite possibly have occurred.

Assuming, therefore, the diagnosis to be correct, Dr. Benson's case remains as the only one in which all other possible sources of origin were excluded and in which practical experience pointed to a communication of the disease from one person to another.

#### 6. THE ALLEGED INCREASE OF LEPROSY.

If leprosy is communicable in any high degree we should expect a rapid increase all over the world, for segregation is not absolute anywhere. In the Sandwich Islands the most strenuous efforts have been made to isolate all the lepers. In 1868, according to official returns, there were 274 lepers. In 1888<sup>5</sup> similar returns showed 749 lepers at Molokai and 644 at large in the rest of the Kingdom. If these figures are correct, we must conclude that segregation in this part of the world has been powerless to check the increase of leprosy. We might, therefore, argue that the increase of the disease depends on other conditions than contact of

<sup>1</sup> *Op. cit.*, page 274.

<sup>2</sup> Dublin Journ. of Med. Sci., June, 1877.

<sup>3</sup> Leloir, *op. cit.*, p. 309.

<sup>4</sup> Monro. Leprosy, p. 45.

<sup>5</sup> Bienn. Rep. of Pres. of Board of Health. Honolulu, 1890.

the healthy with the affected. It is, however, only fair to state that segregation in Hawaii has always been improperly carried out.

In Memel,<sup>1</sup> according to Dr. Rosenthal, there has been a development of leprosy in recent years. Before 1882 no case of the disease was known. In that year a peasant near Memel was attacked and in the next nine years seven new cases occurred. Dr. Rosenthal has not been able to trace the spread of the disease to communication of one person with another or to importation from Russia. Thus, even in places where leprosy appears to have increased, we can by no means argue that it has spread from the diseased to the healthy. If we now turn to some countries where for many years little or no trouble has been taken to insure absolute segregation, we shall find that the published figures by no means bear out the theory of communicability.

*Trinidad.*—Only three official enumerations of lepers have been made in Trinidad since the island was ceded to the English. In 1813 Sir Ralph Woodford, wishing to establish a leper asylum, caused an official inquiry to be made as to the number of lepers in the island. Seventy-three were then found. In 1815 the question of the founding of this asylum came before the legislative council, and the same governor ordered another inquiry. This time the result was 77. The population of Trinidad at that time was given as 32,000. The next and last inquiry<sup>2</sup> was ordered by Sir William Robinson and was completed in 1890. Every effort was made to obtain full returns, the chief sources of information being the district medical officer and wardens. The result showed a total of 414 lepers, of whom 210 were inmates of the leper asylum. The census next year showed the population of Trinidad to be 200,028. Working out the percentages from the above figures, we find that the percentage of lepers in 1815 was 0.242, while that in 1891 was 0.206. It must in fairness be stated that the latter figures are not quite accurate, for the leper enumeration was completed in 1890, while the general census was taken in the next year. The figures, however, are sufficiently approximate. It is greatly to be regretted that no leper census was taken in Trinidad in 1891, as was done in India.

There are several obvious fallacies in any enumeration of lepers: (1) Cases may be overlooked or purposely concealed. (2) Persons may be returned as lepers who are suffering from other diseases. Almost every year patients are sent to the Trinidad Leper Asylum who are found on examination not to be lepers. In India we found that as many as 10 per cent of the cases sent to us were not cases of leprosy. (3) The same case may be reported under two or more names by different observers. A patient in Trinidad frequently has two or three names. (4) There are often several patients of the same name, especially among natives of India. Thus two or more cases occurring in patients of the same name may be put down as one case only. We may regard these different factors as to a great extent counteracting one another, and look upon the figures obtained as conveying a fair idea of the truth. The question may be stated in another way: If there were 77 lepers in a population of 32,000 in 1815, how many ought there to be in 1891 with a population of 200,028? The answer, when worked out, is 481. There is another aspect of the question. The average percentage of deaths at the Trinidad Leper Asylum for the past sixteen years is 11.1. Therefore the number of lepers dying in the whole of Trinidad in a year ought to be between 40 and 50. In 1892, 23 lepers died in the leper asylum, and the registrar general's returns show 27 deaths from leprosy in the rest of the island. The total deaths are thus exactly 50, the number arrived at by the previous independent calculation. The query naturally suggests itself: Do more than 40 or 50 new cases occur in a year? From

<sup>1</sup> Arning. Die Gegenwärtige Verbreitung der Lepra in Europa, 1891, p. 6.

<sup>2</sup> Report on Trinidad Leper Asylum for 1892.

what I know of the western end of the island, which includes Port of Spain, and is the most densely populated and the most infested with lepers, I should very much doubt it. I see a good many new cases, but not nearly enough to suggest a total of 40 or 50 for the whole island. It may be objected that the worst cases are admitted to the leper asylum, and therefore the mortality is higher there; but against this must be placed the fact that good food, hygienic surroundings, and medical and surgical treatment probably prolong life in many patients who would soon die outside the asylum. This view is borne out by the miserable and half-dying condition in which patients are often readmitted after they have been out for some time, and by the rapidity with which they improve again after they have been back a few weeks. From the above considerations it would appear that the available figures for Trinidad show that leprosy has not increased in that island relatively to the population, but, if anything, has slightly decreased.

*India.*—The recently published report of Mr. I. A. Baines, the Indian census commissioner, shows an absolute decrease in the leper population of India since the last census. The results of the two last enumerations are, in 1881, 131,660 lepers; in 1891, 127,056 lepers. There is thus an absolute decrease of 4,604 in the last ten years. Mistakes and omissions no doubt have been made by the native enumerators, but these obtain in both censuses, and the probability is that diagnosis has been more exact in the last enumeration. One very important point requires comment. In the census of 1881 no lepers were returned from upper Burmah, Rajpootana, Travancore, and the Central Province States. The census of 1891 shows 3,504, 1,708, 968, and 1,259 lepers, respectively, for these places, or a total of 7,439. It is, to say the least, extremely unlikely that in 1881 there were no lepers in these four large tracts of country; so that we may conclude that most probably the actual total decrease of lepers in India during the last ten years is very much greater than that shown in the census returns.

*Norway.*—The official returns for the whole of Norway<sup>1</sup> showed in 1856, 2,900 lepers, and in 1885, 1,195 lepers. During this period of thirty years annual leper returns have been made. These show that the disease has been either stationary or decreasing every year, except 1859, when a slight rise is shown. Until 1885 there was no law compelling the isolation of lepers. Dr. Kanria,<sup>2</sup> in a short paper which he sent me the other day, makes the following remarks:

La loi de 1885 sur l'isolement des lépreux a donné lieu à de vives critiques, attendu qu'on l'a trouvée trop rigoureuse. La loi permet en effet dans certains cas, et même sans l'assentiment des malades, à hospitaliser tel ou tel lépreux qui ne peut pas ou ne veut pas vivre dans un isolement suffisamment efficace d'avec sa famille ou son entourage; la loi va jusqu'à permettre la séparation de deux conjoints, après avis préalable du pasteur et approbation du préfet.

Dr. Kanria goes on to show that during the eight years which have elapsed since the law was passed 99 lepers have been admitted to the Reknaes Asylum, of whom only 14 came in by reason of the new law. He does not state what is the present leper population of Norway, but I think the above figures and dates are sufficient to show that the decrease of leprosy in Norway has been almost if not entirely independent of compulsory segregation.

*Iceland.*—The evidence obtained from Iceland is even more striking than that from Norway. Mr. Jealpeson,<sup>3</sup> who visited Iceland last year, writes as follows:

Leprosy, of which I had the good fortune to see a great many cases, is on the decrease in Iceland. The deaths from leprosy in 1768 were 73 per 1,000, and 1868 were 15.7 per 1,000. In 1888, in the south of Iceland, there were known to be only 148 lepers, and in 1892 only about 35. There seems to have been no attempt at segregation in Iceland, and the above figures speak for themselves.

<sup>2</sup> Om Loven af 6te Juni 1885 Angaaende Spedalske Afsondring, p. 9.

<sup>3</sup> Lancet, May 20, 1893, p. 1223.

*North America.*—The parts of North America to which those interested in leprosy first turn their attention are the Northwestern States. Here Norwegian immigration has been going on for the last fifty years. Dr. Charles Hewitt<sup>1</sup> makes the following concise and apposite remarks on an interesting paper by Dr. Gronvald:

It relates, in very conservative language, the experience we have had for the last forty years with leprosy in Minnesota. In no other State that I know of are all known lepers registered and kept under observation and all suspected cases carefully looked into. The history of these cases has been very thoroughly studied. No further isolation than the use of their own beds and utensils is required, and this their own good sense and that of their relatives, as a rule, secures. It must be understood that the state board of health and the local boards have abundant power to enforce the strictest isolation, if found needful; but up to date there has not been any occasion for the use of such power, as the disease is limited to the immigrants, and has never appeared in the descendants of lepers, nor in anyone born in the State.

Dr. Gronvald<sup>2</sup> concludes his paper by the following quotation from Dr. Hansen, who visited America in 1888 to study leprosy in the immigrated Norwegians and their descendants:

Of about 160 lepers who have immigrated into the three States named (Wisconsin, Iowa, and Minnesota) 13 are alive, whom I have seen myself, and perhaps 3 or 4 more. All the others are dead. Of all the descendants of lepers (and that includes the great-grandchildren of some of them), not a single one has become leprous.

Comment on these figures is needless. It is evident that the supervision above referred to only implies a very partial segregation, and in this experience in the Northwestern States of North America we have, I think, one of the strongest arguments not only against heredity but also against contagion.

Summing up the evidence derived from the above five countries we may draw the following conclusions: (1) In Trinidad there has been probably not much change in the proportion of lepers to the general population, but if anything there has been a slight decrease. (2) In India there has been a marked absolute decrease. (3) In Norway there was a steady decrease long before compulsory segregation was thought of. (4) In Iceland there has been a rapid decrease of late years and the disease is now almost extinct, without any attempt at segregation having been made. (5) In the Northwestern States of North America, where leprosy was not endemic, the immigration of Norwegian lepers has not been fraught with any prejudicial results to the rest of the population, nearly all the cases having died out, and no new cases having arisen, in spite of the fact that segregation has only been partial.

From the accumulated evidence detailed in the six sections of this paper I think we may fairly conclude that the risk of communicability of leprosy is so small that for practical purposes it may be disregarded, and that for an explanation of the occurrence of new cases we must look to causes other than association of the healthy with the leprous.

## DISCUSSION.

Dr. OHMANN-DUMESNIL, St. Louis. I have had occasion to see cases which perhaps would support the opinion of the contagionists; a woman physician, who supposed that dissecting a leper in San Francisco caused it. I have also seen cases of apparently spontaneous leprosy in St. Louis. In some of these cases the period of incubation was remarkably short; some two or three years.

Dr. W. S. GOTTHEIL. I believe that in spite of the vast amount of argument pro and con that had been devoted to the subject, from a practical standpoint the

<sup>1</sup> Lancet, March 26, 1892, p. 684.

<sup>2</sup> *Loc. cit.*

question of the contagiousness of leprosy is a very simple one, in this country at least. Isolated cases do not present the same problems as did those in localities where larger communities of lepers exist. Even in these latter the negative evidence of contagiousness is very strong, whilst the positive is very weak. That individual cases are absolutely harmless has been abundantly demonstrated. Three lepers lived for years in the Charity Hospital of New York, in the general dermatological ward. They ate and slept with some thirty other patients, and one of them worked as a deck hand on the island boat. Nevertheless, not a single patient or attendant ever contracted the disease. An occasional leper finds his way into our cutaneous clinics, and undoubtedly others exist in the Chinese quarter. The Chinese, who know the disease better than we do, are not afraid of it. In view of these facts such disgraceful exhibitions as we had recently seen here ought to be frowned upon. To see the Governments of two great and enlightened countries like Canada and the United States bandying a poor sick leper from one to the other across the frontier in a carefully closed box car, and finally shunting him off onto a side track and handling him as if he spread a contagious miasm for a rod around him, is not edifying. And when he finally found a resting place, it was in an isolated tent on the bleakest portion of Blackwell's Island, where he finally died, probably largely on account of his exposure and privations. It is not astonishing that the cry of "leper" in the tenement quarters of the town should cause a panic worse than that of "mad dog," when the ruling and presumably better-educated classes share the absurd prejudice.

Dr. S. POLLITZER, of New York. My own experience of leprosy includes perhaps a score of cases, which I saw cursorily in London, Paris, etc., and half a dozen which I had an opportunity of studying more closely while assistant in Dr. Nuna's clinique in Hamburg. I was much impressed with the admirable presentation of the facts bearing on the contagiousness of leprosy by the reader of the paper before us, though I can not agree with what seems to me the tendency of his argument. The bacilli of leprosy have been found in great numbers in all the affected tissues in every case of leprosy ever examined; in patients the most diverse in race and in geographical position. It is not necessary to dwell on the fact that the germs can not be a mere accidental concomitant of the disease, or that their presence depends on the conditions created by the disease. They must stand in a causal relation to the disease; and if the bacillus produces the disease, leprosy certainly is, in a strict sense, communicable, and directly communicable unless we go back to the theory of an intermediary host as implied, for instance, in Hutchinson's "fish hypothesis," a theory which has absolutely no facts to support it. The failure attending the attempts at cultivation and inoculation can not be denied; but the only conclusion warranted is that the specific organisms or the disease require conditions which have as yet escaped us. The analogy which Dr. Duhring points out in lupus vulgaris of a disease due to a germ but not transmissible is, I must submit, not strictly applicable. Though we can not reproduce the clinical picture of lupus by inoculation, we can cultivate the germ and produce tuberculosis by its inoculation, while in leprosy we can neither cultivate the organism nor reproduce the disease. When Dr. Rake, with his vast experience in this field, has the floor on the rarer manifestations of nerve or trophic lesions in leprosy, most of us can not have much to say. I should merely like to ask in regard to his valuable suggestion for the treatment of perforating ulcer, is not the ulcer itself to be scraped or otherwise treated when the foot is split up? As to the occurrence in pseudo-epidemics of herpes zoster, which Dr. Rake refers to, such occurrences are not uncommon. Epidemics of zona have several times been recorded among children attending a particular school; and we have records of the disease being especially frequent in certain localities. I have been informed that zona is very common in the lower Connecticut valley during the early spring months.

Dr. ALFRED E. REGENSBURGER, of San Francisco, Cal. Dr. Beavan Rake is to be congratulated upon the masterly manner in which he has handled the subject of which this paper treats. Time forbids my discussing it thoroughly, or indeed any one part of it exhaustively. I will, therefore, only touch upon one point and that very superficially. That is with reference to the prevalence of leprosy on the Pacific Coast of the United States, of which San Francisco, Cal., where I reside and practice my profession, may well serve as an exponent, and to which the Doctor, in speaking of its distribution in this country, did not allude. Cases of leprosy can always be found in San Francisco. It is the principal city and metropolis on the Pacific Coast in the Union, as you all know. It has a population of about 320,000, of whom 40,000 are Chinese. These Mongolians are often afflicted with the malady; they are brought into intimate contact with the white population, acting as domestic servants, doing the washing to a great extent, and following other occupations which necessitate their commingling with the Caucasian race. It is necessary to an intelligent comprehension of the question to state here that they employ physicians of their own nationality, persons ignorant of the veriest rudiments of medicine. It follows that if they are suffering from the disease it will escape detection, and if by chance it be recognized, it is more than likely that it will not be reported to the health authorities, as these people are averse to so doing. It is consequently impossible to obtain reliable statistics regarding the disease. What is a still more deplorable state of affairs, if the disease be communicable, is that it is sure to spread. Besides, we are in the direct line of transit to and from the Sandwich Islands, where it prevails endemically, and where, as the Doctor very truly remarked, it is on the increase, and isolation is not as strictly enforced as it should be. There are such a number of cases on the islands that it takes over one-twelfth of the annual revenue to pay for the necessary sanitary supervision and arrangements to care for their lepers. In view of these facts, is it astonishing that any physician; yes, any sanitarian or public-spirited citizen, coming from my section of the country, should be deeply interested in this matter? Still more so, when I tell you that we have in San Francisco a place designed for the reception and treatment of lepers, formerly known as the "pest house," but lately called by the more reassuring name of the Twenty-sixth Street Hospital, where you can always find a dozen or more cases of leprosy, the majority or frequently all of them being Chinese. Now and then it has been customary to ship these patients back to their homes and to the places whence they came. As soon as one batch of Chinese is sent back another lot is there to fill their empty places. Bearing the foregoing facts in mind, I contend that if leprosy be communicable, which I believe it to be, or if there be the slightest doubt concerning its non-communicability, it is no more than right that proper legislative enactments be put upon our statute books and, when there, strictly enforced, looking toward preventing further immigration from these leper-infected countries, and that the most stringent sanitary measures be had recourse to by strict isolation and otherwise to prevent its propagation from those affected by it who are already in our midst. In the present stage of our knowledge it is indubitably our duty to regard the disease as communicable, as that question is sub judice. What rôle may the bacillus lepræ or some other microorganism, of which we know nothing at present, play in making it communicable? I know that someone will ask, and that with reason and justice, Why not do the same, that is, enforce isolation, with phthisis and syphilis? Are they not communicable? Certainly they are. Let me ask, in reply, Do two wrongs make a right? This leads me to ask the question regarding the contagiousness of leprosy. May not the bacillus lepræ bear some relation to that of phthisis? Is it possible to differentiate one from the other by their reactions to coloring agents, bacteriologically speaking? These are interesting questions, which we hope may be elucidated and satisfactorily answered some day, perhaps in our time. Numer-

ous observers have reported cases which they claim were due to contagion, but they are not sufficiently convincing to have settled the matter. You may cite any number of cases where no evidence of communicability can be adduced, yet one affirmative case is of more value than any number of negative ones. To conclude, at the present time I believe leprosy to be communicable. With more light upon the subject the future may lead me to change my opinion.

Dr. WELCH. Having had very little experience in regard to the necrotic lesions in leprosy referred to in the paper, I have but little if anything to say. I have seen quite superficial ulceration in one case, but these ulcers have healed quickly, to be followed by others. I have also seen ophthalmic lesions. Atrophy of muscles, flexor muscles generally, is markedly noticeable in one of my cases.

Dr. DUHRING. I am inclined to agree with the general conclusions of the reader of the paper. Leprosy is not necessarily a contagious disease because associated with a bacillus. Bacilli are found in lupus, but this disease is not, therefore, contagious, at least practically, and the distinction must be made between a disease being practically contagious and one that is only contagious experimentally and under the most favorable conditions. I have noted in some of the cases which I have seen a long period of incubation, in some instances extending over many (ten or twelve) years, that is, from the date the subjects had been in a leprous country or had been in contact with lepers to the period of the first symptoms of the disease. This is remarkable and difficult to explain.

Dr. RAKE. Dr. Welch's case of a woman in Philadelphia who was attacked with leprosy without ever having left the country is a most interesting one, and may be compared with a similar case reported some years ago in Maryland by Dr. Atkinson. The sporadic cases mentioned by Dr. Ohmann-Dumesnil in St. Louis, and Dr. Regensburger in California, are also valuable. It is to these apparently new foci of the disease that we must especially look for information as to the mode of propagation of the disease. Careful and frequent leper censuses in such new foci, together with full notes of any cases observed, will help us far more than observations in countries like India or Hawaii, where the disease has been present for many years and where it is widely distributed. Dr. Duhring has mentioned some very long periods of apparent incubation. In the patients who have developed leprosy in Europe after residence in leprous countries the average period has been, I believe, about two years after their return. This, of course, is open to fallacy, for they may very possibly not have been exposed to leprous infection for several years before returning to Europe.

Dr. Duhring asks what is the general opinion among the other medical men in Trinidad as to the contagiousness of leprosy. Opinion on this point is divided, but I think the majority do not believe that the disease is contagious in the ordinary sense of the word. I have only seen three Europeans in Trinidad who were lepers. Two were German, and one was a Frenchman. I have heard of one or two more.

Dr. Politzer asks how leprosy is propagated if not from one individual to another? I can only suggest the same theory which is believed to be true of tuberculosis. I believe in certain localities leprosy bacilli are always present outside the body, and that residents in these localities are constantly taking the bacilli into their respiratory passages mixed with dust, or into their alimentary canals in food or water. Bacilli are also constantly settling on their skins. Those who are susceptible, from fevers, intemperance, or any other debilitating influence, become lepers, while those in normal health escape. This is of course merely a theory, for we do not yet know the conditions of life of the bacillus outside the body, or whether an intermediate host is necessary for its development before it reaches the human subject.

## LAS AUTO-INFECCIONES EN LA SÍFILIS.

Por el Dr. EDUARDO R. GARCÍA,

*Miembro de la Academia Nacional de Medicina, Profesor de Cirugía en la Escuela Práctica Médico-Militar, Preparador de Fisiología en la Escuela Nacional de Medicina, etc. Representante del Estado de Tabasco, México, en el Congreso Pan-Americano de Washington.*

Durante largo tiempo se ha creído que una gran parte de las afecciones que se presentan en los sífilíticos eran debidas siempre á la sífilis; lo que equivaldría á decir que en un reumático muchas de las afecciones que en él se presentan deberían reconocer necesariamente un origen reumatismal, lo cual está muy lejos de ser cierto. Los que así creyeren seguirían un camino erróneo, sin duda escabroso para ellos y bien peligroso para el paciente.

Pasaron ya los tiempos en los que en presencia de un caso de sífilis bastaba solo hacer el diagnóstico de la enfermedad. Hoy, gracias á los progresos de la patología interna, se disponen de nuevos elementos que han entrado en el dominio del problema patológico. Tan es así, que el conocimiento de la auto-infección ha venido á darnos cuenta de un cierto número de accidentes que se encuentran frecuentemente en los sífilíticos, accidentes que la sífilis sola no bastaría á explicar, y que el tratamiento antisifilítico es siempre impotente para curar.

En efecto, supongamos un enfermo que lleva en la garganta grandes placas mucosas ulceradas, que secretan pús y líquidos más ó menos descompuestos; estos productos en lugar de ser arrojados al exterior son ingeridos por la deglución; ahora bien, ¿que sucedería en este caso? Que el enfermo se intoxicará; que se producirán en él una série de fenómenos morbosos evidentemente independientes de la sífilis que los ha precedido, pero que no ha sido sino la causa ocasional. Esto es precisamente lo que pasa con ciertos accidentes que presentan frecuentemente los sífilíticos, tales como la fiebre, los sudores, las perturbaciones gastro-intestinales y hasta ciertas lesiones faringéas; se produce pues, en este caso, una auto-intoxicación, una infección secundaria, y en los lugares en que por cualquiera causa se establece una erosión ó una ulceración de la mucosa, estas toman desde luego un mal aspecto, que no es debido á la sífilis sino que generalmente depende de la auto-inoculación de los productos sépticos que se escurren de las otras úlceras allí existentes.

Esto es tanto más cierto cuanto que para hacerlas desaparecer no es necesario el tratamiento mercurial, el que muy al contrario frecuentemente las pone en peores circunstancias, y basta solo el esmerado aseo de la cavidad buco-faríngea para conseguir su desaparición.

Podría objetárseme, y con alguna justicia, que el que no desaparezcan estas lesiones bajo la influencia del tratamiento específico, no arguye en contra de su origen sífilítico; es verdad aparentemente, pues que hay algunas que son muy rebeldes á dicho tratamiento, más su rebeldía es ya un dato de presunción, y si á este agregamos los que nos suministran los exámenes histológicos, los análisis micro-químicos, y sobre todo la clínica, tendremos un conjunto de pruebas conspirando todas ellas á un mismo fin, esto es, la separación completa de las lesiones sífilíticas de aquellas que no lo son.

Es también un hecho para todo aquel que haya querido observar bien á los sífilíticos en el segundo período, que su temperatura se eleva en las noches, que sudan más ó menos, y que no pocas veces experimentan un calofrío precursor, que en una palabra, todo este síndrome complejo, llamado comunmente fiebre sífilítica, podrá conducir á un error diagnóstico, atribuyendo á la sífilis lo que en realidad puede reconocer otra causa, como lo diremos luego; y esto solo porque ó no se examina atentamente á estos enfermos, ó se tiene ya una idea preconcebida. Las mismas consideraciones podrían aplicarse á las perturbaciones gastro-intestinales, que reconocen frecuentemente una causa idéntica, la auto-infección.

Mucho tiempo ha que se conocen los fenómenos morbosos determinados por la absorción de líquidos sépticos, tales como los que se encuentran en esta clase de enfermos; y si bien es cierto que se me podría decir que aquí no hay retención de líquidos, tampoco deja de ser cierto que ellos, al caer en la cavidad bucal, son tragados con la saliva y con los alimentos, y una vez absorbidos van á producir los diferentes fenómenos de que he hablado ya. Por qué mecanismo se producen estos accidentes? Bouchard lo ha dicho de una manera magistral en sus lecciones sobre las auto-intoxicaciones, expresándose en los siguientes términos: "El organismo es, en el estado normal como en el patológico, un receptáculo y un laboratorio de venenos; entre estos, unos son formados por el organismo mismo, otros por microbios vegetales inferiores, que son, ó bien los comensales, los habitantes naturales del tubo digestivo, ó bien parásitos advenedizos morbigenos. Así el hombre está constantemente bajo la amenaza de un envenenamiento; trabaja á cada instante en su propia destrucción, hace incesantes tentativas de suicidio por intoxicación y, sin embargo, estas intoxicaciones no siempre se producen. El organismo posee recursos múltiples, para escapar de ellas se descarga de sustancias tóxicas en un recipiente particular, de donde salen en seguida al exterior. La sangre por otra parte subtrae á los órganos los venenos á medida que se forman.

Como es fácil suponer, lo que se acaba de decir podrá tener lugar en el supuesto de un organismo sano, pero en los enfermos de que me ocupo las cosas no pueden pasar así. Ciertamente, en un sifilítico, el estado general domina todas las funciones; en todas ellas se manifiesta cierta languidez, cierto trastorno, y de consiguiente el funcionamiento orgánico se hace mal, pero principalmente el aparato gastro-intestinal en donde se producirán descomposiciones, putrefacciones, etc.; si á todo esto se reúne los productos sépticos venidos de la boca y de la garganta, tendríamos el summum de condiciones favorables para la producción de la auto-infección, la que se revelará por los fenómenos de que he hablado ya, fiebre, sudores, y perturbaciones gastro intestinales, que son todos el resultado de la lucha del organismo para desembarazarse de estos venenos; lucha inútil, pues al fin predomina la acción tóxica, y esto porque el tubo intestinal encargado de eliminar las sustancias nocivas contenidas en el organismo, absorbe al mismo tiempo una parte de ellas que la sangre recoge sin demora, de donde por una parte las deyecciones, por otra los fenómenos de intoxicación, fiebre y sudores.

Así pues, la fiebre en los sifilíticos no es la expresión constante de la infección específica; reconoce, así lo creo, en muchos casos un origen séptico; los sudores son el resultado de la lucha de las celdillas para desembarazarse de estos productos, y los trastornos gastro-intestinales reconocen la misma causa.

Mas aún, accidentes todavía más graves pueden explicarnos suficientemente el mecanismo de las infecciones que vengo describiendo; quiero referirme al aparato renal, que como es bien sabido, es el eliminador por excelencia así de los venenos venidos de fuera como de los que nacen en el organismo. La integridad perfecta del filtro renal, como se le ha llamado, es una condición esencial de su buen funcionamiento, y desde el momento en que por cualquiera causa falta esa integridad, el organismo tendrá que resentir sus efectos. Muchos casos de muerte repentina son un exacto ejemplo de esta verdad.

Ahora bien, Rayer, el primero, y más tarde Lancereaux, Cornil y otros, han demostrado las afecciones renales en los sifilíticos. Estos autores han encontrado en el período secundario la nefritis parenquimatosa ó epitelial, el verdadero mal de Bright sifilítico, la nefritis intersticial en foco, la degeneración amiloide, y en fin, aunque raramente, en el período comunmente llamado segundo-terciario, la goma sifilítica. Todas estas lesiones impidiendo naturalmente la función de los riñones, favorecen la acumulación de productos patógenos en el organismo, produciendo su intoxicación independientemente del virus específico.

A primera vista todas estas cuestiones no parecen merecer toda la importancia que les damos. Sin embargo, si se reflexiona un poco se verá que es absolutamente indispensable conocer á fondo la patogenia de los accidentes de que hablamos, porque si tal enfermo debe ser tratado por el mercurio solo, tal otro tendrá necesidad de una desinfección previa de las lesiones que hayan dado nacimiento á ciertos accidentes de auto-intoxicación. Tan es esto así que el tratamiento debe muchas veces comenzar en ciertos enfermos por la curación de lesiones independientes de la sífilis, tales son los accidentes gastro-intestinales, que como se sabe son una contraindicación para el tratamiento mercurial, pues la integridad de la mucosa del intestino es indispensable para la absorción de las sales de mercurio administradas al interior.

Estando pues probado el papel de ciertas lesiones de la boca y de la faringe en la producción de accidentes graves de auto-infección, el deber del médico queda también perfectamente establecido. Curar estas lesiones antes que los accidentes que ellas producen tengan el tiempo de desarrollarse. Mas para dirigir contra ellas un tratamiento eficaz, el médico debe familiarizarse con estas lesiones, cuyo diagnóstico, si en la mayor parte de los casos es fácil, puede algunas veces presentar muy serias dificultades.

Todos los médicos saben muy bien que una de las primeras manifestaciones del período secundario de la sífilis son las ulceraciones de la garganta, de la lengua y de la boca; pero que las más comunes son las de la región faringea y de preferencia las de las amígdalas, del velo del paladar, y de sus pilares. La región buco-faringea tiene casi exclusivamente el triste privilegio de las placas mucosas. Son casi inevitables en la sífilis, á causa de la irritación constante y forzosa á la cual esta región está expuesta por diversos agentes, tales como el tabaco, el alcohol, y muy principalmente los alimentos, que obran sea por su composición, sea por su acción mecánica. Las placas mucosas así producidas gozan un gran papel en el diagnóstico actual y retrospectivo, como en el tratamiento general de la sífilis.

Muchos sifilíticos, dice Mr. Jullien, suelen escapar de la sífilis grave y de los accidentes terciarios consecutivos, pero se puede asegurar que no hay uno solo que escape de la placa mucosa, de las mucosas; para muchos la sífilis podría reasumirse así: chancro, roseola fugitiva, y á su consecuencia placas mucosas, reincidencia de placas mucosas, y siempre placas mucosas. Mas es preciso distinguir con el mayor cuidado estas ulceraciones verdaderamente sifilíticas de aquellas que no lo son, y que desgraciadamente suelen tomarse con frecuencia como tales, con gran perjuicio del enfermo. Debemos pues diferenciar las ulceraciones que bien pudieramos llamar puras (específicas), y las que son producidas por infecciones secundarias no sifilíticas, y debidas ó á la acumulación de bacterias, ó á irritaciones, ó en fin á la acción especial del mercurio, que es lo más frecuente y á las que de preferencia quiero referirme.

Las ulceraciones propiamente sifilíticas, las sifilides húmedas, llamadas también placas opalinas, tienen caracteres de tal manera propios que en la mayor parte de los casos, y con un poco de cuidado, es bien fácil reconocerlas. En efecto, su aspecto es característico, y aunque varían un poco según el lugar que ocupan, presentan sin embargo caracteres que les son comunes á todas ellas. Así por ejemplo, la angina sifilítica, se caracteriza por una coloración muy especial, rojo frambuesa, pero que no es como dice muy bien Gueneau de Mussy, el rojo vivo de la escarlatina, tampoco es el rojo dorado de la erisipela, ni el rosa subido de los fumadores, sino un rojo carmin que desde luego llama la atención por su rareza, y cuando se produce la ulceración amigdaliana, esta afecta la forma arredondada como si hubiese sido hecha con sacabocado.

En la región estáfilo-amigdaliana, que como ya he dicho es el sitio de predilección de las placas mucosas, al principio se distinguirían por un engrosamiento circunscrito del epitelio y una especie de despulido, una simple erosión; mas es raro

observarlas en este estado porque generalmente los enfermos no reclaman nuestros cuidados sino cuando han avanzado mucho más, cuando está ya constituida la verdadera ulceración, y entonces se nos presentan con los caracteres siguientes: Son ovalares y no talladas á pico como se cree comunmente, pues la forma alargada é irregular que presentan á primera vista es debida al plegamiento de ellas siguiendo el borde palatino. Su fondo es sucio, cubierto de una escara blanquizca que no se le puede desprender ni con el lavado, es más bien un exudado difteroiide; son poco ó nada dolorosas, y el enfermo acusa cuando más una sensación de picoteo y de molestia en el momento de la deglución.

Si la ulceración es más vasta y profunda, su coloración es amarillenta y su aspecto pultaceo, sus bordes engrosados, y entonces si son dolorosas in situ y á distancia, propagándose el dolor á los oídos, y aún no es raro que los ganglios sub-maxilares se infarten.

En cuanto á las ulceraciones de los labios, de las encías y de los carrillos, son más frecuentemente opalinas, y desde el principio se complican de exudaciones difteroides. Si no se les atiende en su marcha, los estragos que producen son considerables, su aspecto se hace exuberante simulando verdaderas vegetaciones.

Ahora bien, las ulceraciones de la boca ó de la garganta que más á menudo son confundidas con las específicas, son las mercuriales; aunque hay otras que producidas por distintas causas presentan cierta analogía con las primeras, tales son por ejemplo, las ulceraciones de los labios y de los carrillos en los vidrieros, la placa mucosa lingual simple, la psoriasis lingual dartrosa, las placas de los fumadores, la estomatitis úlcero-membranosa, y por último el chancro sifilítico mismo; mas de todas estas lesiones las primeras son bien raras, la penúltima es casi propia de la infancia, y la última tiene su bubón que la acompaña fatal y constantes mente. Así pues describiré solo las mercuriales, que son en mi concepto las más frecuentes, las más graves, y las que presentan mayores dificultades para su diagnóstico.

En efecto hay casos en los que más bien por deducción que por convicción se supone su naturaleza, y como una prueba de tan inmensa dificultad citaré aquí textualmente el siguiente hecho tomado de la Clínica Médica de Bennette:

Pour moi, j'en suis convaincu, les sujets dont l'organisme est imprégné de mercure, sont fréquemment affectés d'ulcères que l'on prend tous les jours pour des ulcères syphilitiques. Le cas suivant, dont j'ai été témoin il y a quelques années, est un des premiers qui ont appelé mon attention sur ce sujet. Une petite fille, âgée de 7 ans, venait d'entrer à l'hôpital chirurgical. Elle avait, sur la partie moyenne du tibia, un ulcère arrondi ayant tous les caractères de l'ulcère vénérien, décrit par Hunter. D'après les renseignements recueillis, il paraît que l'enfant avait souffert des dérangements intestinaux, et la mère avait jugé bon d'aller chez un droguiste, demander des poudres purgatives. On lui remit 12 paquets d'une poudre blanche très fine; elle en donnait un le matin et un le soir; au bout de quatre jours survint une salivation abondante; cependant on n'en continua pas moins de donner les poudres restantes, ce qui produisit un état cachectique. Sur ces entrefaites, l'enfant reçut un coup violent sur la jambe, et c'est à la suite de cet accident que se produisit l'ulcère mentionné. Jamais il n'y avait eu de trace de syphilis dans la famille et tous les parents étaient en parfaite santé. Le professeur de clinique, le regretté Syme, déclara publiquement que si cette enfant avait eu dix-sept ans au lieu de sept, trompé par les apparences, il aurait cru à un ulcère syphilitique.<sup>1</sup>

Como se ve, profesores tan eminentes como el clínico inglés citado por Bennette se han encontrado perplejos y embarazados ante el diagnóstico de una ulceración de origen mercurial, y esto sobre la piel en donde son extremadamente raras.

Fácilmente se comprenderá lo que puede suceder cuando tales ulceraciones ocupen sitios de predilección como la boca y la garganta, comunes á las dos variedades, específicas y mercuriales.

<sup>1</sup> Tomo 2º, pág. 669.

Sin embargo, señalaré los caracteres clínicos que he podido observar como distinguiendo esta especie de ulceraciones y que podrán servir en la mayor parte de los casos para diferenciarlas y reconocerlas; comienzan generalmente por un enturbiamiento, digámoslo así, difuso del epitelio, hay desde luego formación de una capa gris sucia que la cubre, no bien circunscrita, muy semejante á la grasa ordinaria, pero que puede desprenderse más ó menos por un lavado anti-séptico apropiado. Se nota un inchamiento considerable de la mucosa gingival y faríngea, de un color lívido y sangrando fácilmente. Son dolorosas al apretar los dientes ó en el momento de la deglución, producen salivación abundante, y en fin se exacerban bajo la influencia del tratamiento específico, en tanto que las verdaderamente sífilíticas son siempre modificadas favorablemente por el mismo tratamiento.

El exámen microscópico podría también probablemente dar algunos elementos de diagnóstico. Así, en las ulceraciones sífilíticas se encontraría en los puntos donde falta la capa pultacea, además de celdillas pequeñas que forman la base de toda ulceración (leucocitos), las celdillas más grandes características de los procesos sífilíticos, y quizás el bacilo de Lustgarten contenido en ellas. En cambio, en las ulceraciones mercuriales, además de que el exudado que cubre la ulceración no es tan abundante, solo se encontrarían en él las pequeñas celdillas antes citadas.

Por otra parte, raspando una ulceración sífilítica podría obtenerse algunas celdillas con el bacilo de Lustgarten, y en este caso el diagnóstico sería seguro, pero como tales celdillas ocupan habitualmente capas relativamente profundas, no se pueden obtener siempre en cada examen. Por último, no sería imposible encontrar el bacilo mismo libre entre las granulaciones del pus.

Debo á la benevolencia y al talento de mi distinguido compañero y amigo, el Dr. M. Toussaint, un medio de diagnóstico químico que le pertenece, y que es de grande utilidad para reconocer las ulceraciones mercuriales: consiste en recojer la saliva que en abundancia escurre de estas ulceraciones y someterla á las reacciones del mercurio; con frecuencia se encuentra este metal en exceso.

Tales son los medios que la ciencia ofrece al práctico para reconocer, y por consiguiente, tratar algunas lesiones de importancia en apariencia secundaria, pero de donde nacen por el mecanismo de la auto-infección cierto número de accidentes de una gravedad considerable.

---

#### DISCUSSION.

Dr. RAVOGLI. I am very glad to make a few remarks on the paper of Dr. Garcia, which I find very scientific and of great practical interest. I will limit myself to a few points which have attracted my attention. The existence of a syphilitic fever I am not prepared to deny. I would, however, have that syphilitic fever not mixed with any other fever which may arise in a syphilitic by the reabsorption of the purulent matters from ulcerations. When the syphilitic virus from the lymphatics passes into the system, producing systemic troubles, when the syphilitic erythema appears, then the patient begins to suffer with headache, backache, loss of appetite, feels tired, and loses all his ambition, and in this case some intermittent fever appears. I would not be opposed to calling this fever syphilitic fever, which is nothing else than reaction of the organism to the syphilitic virus. I will not call, however, a syphilitic fever the fever which is sometimes produced by the presence of ulcerations, secondary or tertiary, by the absorption of their purulent and fermentative substances. When the kidneys are concerned, I must say that in the secondary period of syphilis I have very seldom met with kidney derangement. Often I examine the urine of my syphilitic patients, but very seldom find traces

of albumin. Two syphilitic patients in my practice died with parenchymatous nephritis, whose origin I must recognize from syphilis, but syphilis was in the late period. Mercurial ulcerations I have never seen, and all the ulcers, either on the mucous membranes or on the skin, were only the result of syphilis. In the treatment of my patients I am very careful; as soon as that slight sign of stomatitis happens, I stop the administration of mercury. In all the ulcerations with which I had to do I saw always the mercurial treatment act very beneficially. In regard to the disturbances of the gastro-intestinal apparatus, I can say that I very seldom saw them in my practice, and in pretty nearly all my cases the trouble had its origin in the way of administering mercurials. When especially protiodide or biniodide of mercury is given very often stomach catarrh arises, and in these cases on stopping the internal use of mercurial preparations the intestinal and gastric symptoms disappear. I will not, however, exclude the possibility of the presence of ulcerations in the stomach and in the intestines, as we often find ulcerations on the pharynx. The mucous plaques and the ulcerations of the mouth and of the throat must be treated locally, carefully washed and touched, but the general treatment can not be stopped, either in form of subcutaneous injections or by inunctions, as this is the fundamental therapeutic means for their treatment.

Dr. LOUIS A. DUHRING, of Philadelphia. I am not disposed to make remarks upon the paper as a whole, but, desire to express my views merely on one point touched on, namely, the influence of the syphilitic virus upon the pathological processes that might occur during the life of the individual. I believe that this virus may give rise, and in most cases does, to certain distinct so-called syphilitic manifestations in the various tissues of the body, but that in some other cases it influences, in a variable measure, other pathological processes which may exist, especially those of a chronic nature. In this case it becomes a question which process is the more active and virulent on the body. One generally predominates and holds the other in submission, at least for a time. The complications which syphilis may give rise to are not thoroughly appreciated in the works on medicine, whether general or special. We must recognize the fact that so-called "mixed diseases" may and sometimes do occur. They constitute some of the "unclassifiable cases" that we occasionally meet with.

Dr. RAKE. I have seen several cases of syphilis associated with leprosy, and have often had great difficulty in determining to which disease the various lesions met with were due. In autopsies I have sometimes found the lesions of the two diseases side by side. I have seen syphilitic degenerations in the viscera, together with leprosy deposits in the larynx. On the other hand, I have in some cases had great difficulty in deciding whether caries of the nasal bones and destruction of the epiglottis are due to syphilis or to the leprosy processes which we know occur in these tissues. During life I have seen gummata develop in a leper and clear up in a short time, under mercury and iodide, while the course of the leprosy has been unaffected. It would thus appear that sometimes one disease may be unaffected by the other, while in other cases the lesions of leprosy, and those of syphilis become almost hopelessly mixed. We of course remember that it was formerly believed that leprosy was a form of syphilis, but this theory has long been entirely abandoned.

Dr. WELCH. I am led by the discussion to make but a single remark, which is that the existence of syphilis, so far as my experience goes, does not exert any influence over smallpox. What it may do in chronic disease I can not say, but I have frequently seen syphilis, in some one of its three stages, exist in smallpox patients without the one disease, so far as I could see, changing to any degree the course of the other.

Dr. OHMANN-DUMESNIL. I have seen syphilis modify other diseases. As Dr. Duhring remarked, it is the chronic manifestations which are thus influenced. I

have seen a chronic eczema of many years' standing disappear after the evolution of syphilis. I have also seen psoriasis disappear, a conclusion which was rather unexpected in view of the fact that squamous syphilides are so prone to occur. On the other hand, the syphilitic process produces lesions, non-specific in character, although marked, and requiring treatment non-specific in character.

Dr. GARCIA. The points more interesting in my paper are *lésion gutturale de la langue*, etc., produced by the mucous plaques, or by any other irritant, tobacco smoking, or by the nutritive substances, or from the abuse of mercury, producing virulent fluids, which are swallowed into the stomach, and when they are absorbed they produce an auto-intoxication, the symptoms of which are the diarrhoea, loss of appetite, etc., and then the fever, which is not the manifestation of the syphilis, but a reaction of the system to get rid of these poisonous substances.

Dr. G. CLOTURE. I do not believe that the fever to which Dr. Ravogli has called attention has anything to do with the fever to which I call attention. We have more important diseases of the skin where no fever exists. In the patients of which I speak no dermatosis is present, they are getting pale, they have fever at night, etc., and when we look in the mouth or on the throat we find mucous plaques, from which a great quantity of purulent matter comes. For these patients let the mercury alone and use asepsis of the mouth and of the throat, and in a few hours we will see an improvement. In renal affections, Ravogli says that he has not found albumin in the urine. I think that is true, as the albumin does not appear on account of the mercurial treatment; but diseases of the kidneys have been found at the autopsy. These diseases have been developed by the syphilitic process. Syphilis does not always produce syphilitic lesions. In cases of pneumonia, syphilis stops until the acute-disease is finished; the same in cases of trauma. During the process of smallpox syphilis stops, and the acute disease continues its course. It is difficult to make the differential diagnosis between the mercurial ulcerations and the syphilitic ones. The syphilitic ulcers are sharply cut. The mercurial ulcerations are of the same aspect. The syphilitic ulcerations are dull red; the mercurial ulceration is covered with a diphtheroid mass which is easily detached. In the syphilitic ulcers *Lustgarten bacilli* are found, and not in the mercurial.

## A CASE OF INTERMITTENT PRURITUS.

By A. H. OHMANN-DUMESNIL, of St. Louis.

Pruritus is one of the neurotic disturbances of the skin which has never lost interest for the student of cutaneous disorders. As it is embraced in the great class of diseases whose symptoms are entirely symptomatic and whose etiological factors have a greater or less obscurity clouding them we are more or less attracted to their further study, and this is one of the chief reasons why I desire to place on record a case which is unique in my experience and of which I have not seen a similar record in my reading. To begin with, I will first detail the case, reserving any observations for further discussion to a later time. I desire to premise that the patient is still a resident in my city and is occasionally seen and that at latest accounts the condition which I am about to describe remains unaltered, although it is but just to remark that no treatment whatever has been attempted up to the present:

Mrs. W. is a woman of medium height, who is well nourished. She has a good suit of brown hair, that on the pubes and in the axillæ being also of good growth. She is 29 years of age. Her menstruation was always normal and regular previous to her marriage, which took place when she was 16 years old. When 17 years of age she bore a child, which is now 12 years of age. At this time (that of delivery) she experienced quite an extensive laceration of the cervix uteri. A series of domestic troubles culminated in her taking 4 ounces of tincture of opium on March 6, 1889. Through the strenuous efforts of the physicians called in to treat her she was saved, and her next menstrual period occurred on April 16 of the same year. It is from this time that her present trouble dates. She has been observed in her attacks, and they all resemble each other. Before, during, or immediately after menstruation she is the subject of an intense pruritus, which attacks the entire integumentary surface. The itching is equally severe everywhere, and no amount of scratching will relieve it. An attack will continue for twenty-four to thirty-six hours, although at first the duration was three days. Among the peculiarities observed during an attack is that the face assumes an intense red color, and in addition to this the pupils contract to one-third the normal size. Another peculiarity is that the most violent scratching produces no lesions whatever. It sometimes happens that an attack of the trouble is missed, yet the patient will continue to menstruate normally at regular periods. Not long since (July, 1893) she was successfully operated upon for her laceration, but the attacks of pruritus have recurred since. This patient has never taken opium nor any narcotic since the poisonous dose referred to above, and she was not addicted to their use prior to that event. In fact, she has never taken medicine of any kind at any time unless it be a little extract of peppermint or a mild saline cathartic. A fact which has been observed is that the attacks grow milder every year, despite the circumstance that she has never been treated for the trouble. This woman is peculiarly nervous in disposition. She is restless, and when awake has a habit of tearing paper into small pieces, and has in general destructive impulses of a mild character. She is of a passionate disposition, and the sexual orgasm is of an intense character in her case. She is also inclined in a great degree to erotomania, being upon the very verge of being an erotomaniac, although not suffering from nymphomania.

This case offers some peculiarities which to my mind are not easy of solution. The etiological factors are far from being clearly defined. The pruritus can not be said to depend upon any uterine disorder, for it did not occur before to the date of the opium poisoning. On the other hand, the ingestion of the narcotic cannot be directly called upon as a factor in the production of the itching. Whilst we know that opium and some of its alkaloids produce pruritus, this subjective trouble disappears upon the cessation of the action of the medicament. Of course it may be said that the ingestion of such a large quantity of opium produced a certain effect upon the nerve centers and that this was perpetuated, but it is merely restating facts as they exist. The regularity of the appearance of these attacks, with a possible few exceptions, is analogous to some other conditions which have been observed in connection with certain cutaneous affections, notably recurrent

exfoliative erythema, or closely resembling the recurrent attacks at regular intervals which are observed in certain diseases which are supposed to be of nervous origin, such as hay fever, epilepsy, etc. The fundamental cause of this periodical recurrence has never been definitely ascertained, and I must perforce be satisfied in simply recording an interesting condition and confess my inability to account for it in any manner which would be either adequate or satisfactory.

---

### DISCUSSION.

Dr. POLLITZER, of New York. I should merely like to lay some stress on the fact that the case described by the author of the paper belongs to the class of reflex neuroses connected with the menstrual function. I have in mind the herpes progentalis and H. labialis, which recurs sometimes regularly with each menstrual epoch. I have known a case in which herpes labialis recurred for a period of nearly two years, during which the patient was under observation every four weeks, at the end of the catamenia. Reflex neurosis associated with menstruation and pregnancy are not at all uncommon, though the case of the author is well worth recording and is in some respects unique.

Dr. OHMANN-DUMESNIL. Dr. Duhring does not regard the case as unusual, because it is known that nervous troubles occur at this time. Yet cases of this sort have not been reported. So far as secondary lesions are concerned, I have frequently seen them follow pruritus of the anus, and many cases also did not show any marks. But in the case which I have detailed there was evidently some trouble at the base of the brain, as evidenced by the flushing of the face and contraction of the pupil.

---

### A STATISTICAL RECORD OF 5,000 CASES OF SMALLPOX.

By WILLIAM M. WELCH, M. D.,

*Physician in charge of the Municipal Hospital for Infectious Diseases, Philadelphia, Pa.*

Recognizing the difficulty of interesting an audience by the narration of statistics simply, I have concluded to present the facts which I have to offer somewhat after the style of an object lesson. I shall mention but few facts that can not be seen clearly illustrated in the tables hanging before you. Before calling your attention to these tables I should say that the opportunity to study and classify these 5,000 cases of smallpox was afforded me in the Municipal Hospital for Infectious Diseases, of Philadelphia, during the period from 1870 until the early part of the present year. This period includes several epidemics of the disease, some of which were of considerable magnitude and great virulence—notably, the epidemic of 1871-'72, which was almost world-wide and everywhere marked by unusual malignancy. During such visitations of the disease a very large proportion of the severe and malignant cases were found among the admissions to the hospital. This is owing to two facts: First, since removal of patients to the hospital was not compulsory, most of the milder cases were treated at their homes; and, secondly, that a very large proportion of the patients were received from the lower class of society, with constitutions exhausted or depraved by intemperance and other depressing habits. Even many of these were not received until all hope of recovery had passed. During the epidemic of 1871-'72 as many as 128 patients died in

less than forty-eight hours after admission, while, indeed, a few others died in the ambulance on their way to the hospital, and all such are, of course, included in the statistics to be submitted. I mention these facts in explanation of the unusually high death rates to be seen in the tables. But while the death rates are unusually high there is no disproportion in this respect between the vaccinated and the unvaccinated cases. That is to say, if the death rate is excessively high in the one, it is to an equal degree excessively high in the other. There will, therefore, be no difficulty in measuring by these statistics the value of vaccination as a protective or modifying agent in smallpox. The first table to which I shall call attention is one showing the cases classified accordingly as the disease was unmodified or modified. The former type, of course, is designated variola, and the latter, varioloid, while the term smallpox, whenever used, must be understood as including both.

TABLE 1.—*Showing the cases divided into variola and varioloid.*

| Disease.       | Admitted. | Died. | Per cent of deaths. |
|----------------|-----------|-------|---------------------|
| Variola.....   | 2,831     | 1,534 | 54.18               |
| Varioloid..... | 2,169     | 28    | 1.29                |
| Total.....     | 5,000     | 1,562 | 31.24               |

All unvaccinated cases, all malignant cases, and all vaccinated cases in which the eruption advanced to the pustular stage and was attended by well-marked secondary or suppurative fever have been classified in this table as variola; while all the vaccinated cases in which the eruption was markedly abridged in its course, and in which there was little or no secondary rise of temperature, have been classified as varioloid. According to this classification a fatal result almost never occurs from the latter, except in greatly enfeebled constitutions or when some complication arises. While the death rate was 54.18 per cent from variola, it was only 1.29 per cent from varioloid.

TABLE 2.—*Showing the cases classified according to the sex of the patients.*

| Sex.        | Admitted. | Died. | Per cent of deaths. |
|-------------|-----------|-------|---------------------|
| Male.....   | 3,261     | 1,031 | 31.61               |
| Female..... | 1,739     | 531   | 30.54               |
| Total.....  | 5,000     | 1,562 | 31.24               |

The table shows that a considerably larger number of males than females was admitted to the hospital, and also that there is practically no difference between the death rates of the two sexes. Although the preponderance of cases is on the side of males, yet it can not be said that sex exerts any influence whatsoever over susceptibility to smallpox, nor that the disease, all things being equal, is more fatal among one than the other. It is true that men are more frequently addicted to intemperance, and that this habit predisposes to malignancy of the disease; but, on the other hand, pregnancy in women is very liable to be followed by abortion, and when this accident occurs it always proves to be a very serious complication.

TABLE 3.—*Showing all the cases classified according to the color of the patients.*

| Color.     | Admitted. | Died. | Per cent of deaths. |
|------------|-----------|-------|---------------------|
| White..... | 4,200     | 1,221 | 29.07               |
| Black..... | 800       | 341   | 42.62               |
| Total..... | 5,000     | 1,562 | 31.24               |

It is generally believed that smallpox is more fatal among colored persons than among whites, and the above table seems really to support such a belief, but before a reliable conclusion can be arrived at it is necessary that the patients of both colors should be observed under precisely the same circumstances; that is to say, comparison should be made between the unvaccinated of each color. Such a comparison may be seen in the following table:

TABLE 4.—*Showing the unvaccinated cases of smallpox classified according to the color of the patients.*

| Unvaccinated. | Admitted. | Died. | Per cent of deaths. |
|---------------|-----------|-------|---------------------|
| White.....    | 1,173     | 681   | 58.05               |
| Black.....    | 439       | 257   | 58.54               |
| Total.....    | 1,612     | 938   | 58.18               |

Reference to the last two tables shows that of the two classes of patients, white and black, a very much larger proportion of the blacks were unvaccinated. Of course that accounts for the greater percentage of deaths among this class in the former table. In the latter table, however, where a comparison can be made between the unvaccinated of each color, it is seen that there is practically no difference in the death rates, the deaths among the whites being at the rate of 58.05 per cent and among the blacks 58.54 per cent. I would not presume to say that all the observers who contend that smallpox is more fatal among negroes than whites are mistaken in regard to their observations, but I wish to emphasize what I have already said, that no conclusion on this point is reliable unless both of these classes of patients have been observed under precisely the same circumstances.

TABLE 5.—*Showing the cases classified according to the vaccine condition of the patients.*

|                                             | Admitted. | Died. | Per cent of deaths. |
|---------------------------------------------|-----------|-------|---------------------|
| Vaccinated in infancy, good cicatrices..... | 1,412     | 124   | 8.78                |
| Vaccinated in infancy, fair cicatrices..... | 666       | 98    | 14.71               |
| Vaccinated in infancy, poor cicatrices..... | 1,070     | 290   | 27.10               |
| Post-vaccinal cases.....                    | 3,148     | 512   | 16.26               |
| Unvaccinated cases.....                     | 1,759     | 1,027 | 58.38               |
| Unclassified cases.....                     | 93        | 23    | 24.73               |
| Total.....                                  | 5,000     | 1,562 | 31.24               |

In this table a comparison may be made between the vaccinated and the unvaccinated cases. For reasons already stated, the proportion of deaths in both cases is excessively high. Among the unvaccinated it is as high as 58.38 per cent, and among the vaccinated, as a whole, 16.26 per cent. Although high, the difference between these death rates is very striking. If the 1,759 unvac-

inated cases had been vaccinated in infancy similar to the others, instead of 1,027 deaths among this class, there would have been only 286, a saving of 738 lives. Vaccination would have accomplished even more than this for these patients; it would have so modified the disease in a large proportion of those that recovered as to have preserved them from disfigurement for life.

In examining the cicatrices of a large number of persons it is found that these scars differ considerably in appearance, and the question naturally arises, can protection be measured to any degree by the different characteristics which they present? There is no doubt that many persons with quite inferior vaccine marks are fairly well protected or even enjoy immunity from smallpox, while many with typical marks prove to be susceptible to the disease, and indeed often perish from it. But such results must, I feel sure, be regarded as exceptions to the rule. When a large number of patients are examined and the results tabulated, as the above table shows, the degree of protection, as indicated by the death rates, is found to bear a very close and direct relation to the character of the vaccine cicatrices.

All of the patients represented in the tables were carefully examined on their admission to the hospital, and the number and character of their vaccine scars at once recorded. At this time it was of course generally impossible to foretell the final result. The scars were divided, according to their quality, into three grades, which are designated in the tables by the terms "good," "fair," and "poor." Under the first head I have classified all cases presenting typical vaccine cicatrices; that is to say, cicatrices which are distinctly excavated, with well-defined margins, reticulated or foveolated, and altogether presenting the appearance of having been stamped into the skin by a sharply cut die. Under the second head I have classified all cases with scars having the same general characteristics, though much less distinctly marked. Under the third head have been classified all cases having scars which were said to have been the result of vaccination, but which in very many instances were so indistinct or uncharacteristic as to make it difficult, and sometimes even impossible, to recognize them as vaccine scars. The cases classified under the heads of both "good" and "fair" marks had all, doubtless, passed through a well-marked, or reasonably well-marked, course of vaccina in infancy. The death rates are respectively 8.78 and 14.71 per cent. But I am strongly of the opinion that very many of the cases classified under the head of "poor cicatrices" were never successfully vaccinated. Very often I felt fully convinced at the time of making the examination and recording the vaccine condition that such was the case, but as the patients insisted that they had been vaccinated I could not reject their testimony without being considered, especially by the enemies of vaccination, a partial judge. It certainly does not detract from the reputation of vaccination to know that when the vaccine process is irregular, imperfect, or spurious the protection is diminished or absent. As the mean death rate of the cases showing "good" and "fair" cicatrices is 10.68 per cent, and the death rate of those showing "poor" scars is 27.10 per cent, it is evident that not only very many of the latter had been imperfectly vaccinated, but that a large number had never been subjected at all to the vaccine process.

It is impossible to illustrate in this table the very striking and conclusive evidence of the protective power of vaccination that frequently came under my notice while observing these 5,000 cases of smallpox. Such, for instance, as witnessing on the one hand an unvaccinated person suffering from the confluent form of the disease, loathsome and offensive, with the final issue for several days uncertain, and on the other hand a vaccinated person undergoing a modified form of the disease so mild and innocent in its character as not to excite any apprehension for the safety of the patient. In the former case, if recovery took place, the individual was left disfigured for life, while in the latter, after a few months

had passed, there was but little, if anything, in the appearance of the individual to indicate that he had ever suffered from the disease at all. Also, I have seen over and over again entire families brought into the hospital when all the unvaccinated children have been suffering from smallpox and the vaccinated children unaffected; have seen the former perish and the latter remain exempt from the disease, although living, eating, and sleeping in the infected atmosphere for several weeks; but I have yet to see a single unvaccinated child escape the disease under similar circumstances. Furthermore, I have more than once seen a vaccinated infant draw its daily supply of nourishment from a mother suffering from varioloid and the infant remain as free from any symptom of the disease as if the infection were a thousand miles away and the food were received from a most wholesome source. All this is evidence of the prophylactic power of vaccination that can not be seen in mortality tables.

Under the head of "unclassified cases" in the last table are included quite a large number of patients who were vaccinated after exposure to the variolous infection, and also a few patients who died and were buried before an examination as to their vaccine condition could be made.

The next table to which I shall direct attention is one illustrating the comparative efficacy of vaccination as performed in various countries, especially in the United States, Germany, and Ireland.

TABLE 6.—*Showing the cases classified as to nationality of the patients and their vaccine condition.*

| Post-vaccinal cases..... | 8              | 4     | 50.00     |

Perhaps I should explain, in the first place, that the high rate of mortality exhibited under the head of "unknown" nativity is owing to the fact that many of the patients therein represented were foreigners apparently, and were received into the hospital in a moribund state, so that it was impossible to learn their nationality. I may add, also, that under the heading of "other nativity" are included the patients who were natives of the various countries of the globe not designated in the table, excepting China and Japan. Referring to the table, it is seen that under the three nationalities given the death rates of the unvaccinated cases of the United States and Germany do not differ materially, but the death rate of the unvaccinated cases of Ireland is very much higher. A comparison of the post-vaccinal cases also shows that the vaccinated patients of Irish birth have perished in the largest proportion. This seems to indicate that smallpox is most fatal among the Irish; a fact which I believe I have noticed in every epidemic of the disease that I have witnessed. The difference between the rates of mortality among the cases showing "good" marks, as is seen under the three nationalities mentioned, is not great, and the slight difference that does exist may be entirely accidental. But the difference between the death rates of those showing "poor" marks is very great, and decidedly in favor of the patients of German birth. The vaccinations performed in Germany prove to be more uniformly protective, and hence the death rate among the post-vaccinal cases under this head is the lowest of any of the nationalities. All this seems to prove that vaccination is most efficaciously performed in Germany. The comparative exemption of Germany and the German army from smallpox is simply a striking example of the brilliant result of careful and efficient vaccination. When most of the vaccinations represented in the table were performed it was customary in the United States, and in Ireland also, I believe, to use humanized crusts; but in Germany fresh eight-day lymph or arm-to-arm vaccination was the means or method employed, and this is calculated to give the very best results. Hence I think it is not improbable that the German patients owe their better protection to the superior quality of the vaccine lymph generally employed in their country. There is another explanation that might be offered to account for the superior protection enjoyed by the German patients, namely, that it is the practice in Germany in performing vaccination to make numerous insertions of the vaccine virus. In examining the arms of German patients it is quite common to find three distinct scars on each arm, and even a greater number is frequently met with. I have seen as many as twenty typical vaccine marks on the arms of a German patient. If multiple insertions of the vaccine lymph increase the protection against smallpox—and statistics are not wanting to show that such is the case—surely German subjects should be well protected. But, in view of the facts which will appear in the following table, I am inclined to believe that the Germans owe their superior protection from smallpox more to the quality of the vaccine virus they use than to the number of insertions they make.

TABLE 7.—*Showing the cases classified as to the number and character of the vaccine scars borne by each patient.*

|                                                                                      | Ad-<br>mitted. | Died. | Per cent. |

| Vaccinated in infancy:                                                               |                |       |           |
| Three good marks.....                                                                | 119            | 10    | 8.40      |
| Three fair marks.....                                                                | 45             | 4     | 8.88      |
| Three poor marks.....                                                                | 49             | 13    | 26.53     |
| Total.....                                                                           | 213            | 27    | 12.67     |
| Vaccinated in infancy:                                                               |                |       |           |
| Four or more good marks.....                                                         | 247            | 24    | 9.74      |
| Four or more fair marks.....                                                         | 80             | 10    | 12.50     |
| Four or more poor marks.....                                                         | 97             | 11    | 11.34     |
| Total.....                                                                           | 424            | 45    | 10.61     |

\* The cases classified in this table as claiming to have been vaccinated, but showing no visible mark, are included in the other tables among the unvaccinated. So, also, quite a number of those classified in this table as having been vaccinated during the incubation period of smallpox are included among the vaccinated or unvaccinated in some other tables, which fact will explain some discrepancies.

The first thing to be seen in this table is that there is practically no difference between the death rates of the unvaccinated patients and those claiming to have been vaccinated but showing no visible mark. This proves that there was either a mistake as to the alleged fact, or that a vaccination which is followed by no mark is devoid of protective power. The table also shows that vaccination practiced after exposure to the infection of smallpox may afford considerable protection against the disease. If it be performed within two or three days after the infection has been received into the system it is possible for the protection to be absolute. I have seen as many as 28 children perfectly protected from smallpox by vaccination during the incubation period.<sup>1</sup> But if the vaccination be performed much less than seven days before the eruption of smallpox appears, no modifying influence will be exerted. A considerable number of the cases included in the above table under the head of "vaccinated seven days and less, prior to the appearance of the variolous eruption," had been vaccinated no longer than from two to four days before the eruption appeared, while a somewhat larger number had been vaccinated as long as from four to seven days before it appeared. Taking the whole number of cases under this head, it is seen that the death rate is 43.86 per cent, while among the unvaccinated it is as high as 58.18 per cent. This shows that considerable protective influence must have been exerted by vaccination performed

<sup>1</sup> For further information on this subject, see my paper on "Vaccination During the Incubation Period of Variola," published in the Transactions of the Ninth International Medical Congress, Vol. IV, p. 160.

during that period. But a still greater influence was exerted among the cases included under the succeeding head, where vaccination is represented as having been performed longer than seven days before the smallpox eruption appeared. The death rate here is only 20.27 per cent. In regard to the matter of estimating the efficacy of vaccination by the number of vaccine cicatrices borne by each person, the table can not be said to support the views of most authors, nor does it accord with the experience of some other observers. It is indeed in striking contrast with the evidence on this point collected by Mr. Marson and tabulated by Mr. Simon. According to these authors, who derived their data from 6,000 post-vaccinal cases of smallpox, the mortality rate among patients having 1 vaccine scar was  $7\frac{1}{2}$  per cent; having 2,  $4\frac{1}{8}$  per cent; having 3,  $1\frac{3}{4}$  per cent; having 4 or more, three-fourths of 1 per cent. Where the vaccine scars were all well-marked or typical, the loss by death is said to have been even less than is here indicated. The table shows, it is true, that the highest death rate is among the patients having but 1 vaccine mark, but unquestionably this is owing to the fact that a very much larger proportion of the patients under this head than under any other showed "poor" marks, and, as already pointed out, very many of these patients would be more correctly classified if counted among the unvaccinated cases. Those having 4 or more "poor" marks are in a much smaller ratio to the total number of post-vaccinal cases under that head than under any other, and the death rate, to be sure, is remarkably low. It is indeed almost as low as among those showing 4 or more "good" marks. The explanation of the low death rate here is that nearly all the patients classified under this head were natives of Germany, where, as already shown, vaccination is so efficiently performed that if the scars are not in every respect typical there is nevertheless well-marked protection.

Referring again to the table, it is seen that where the vaccine scars are typical there is no relation between the number of such scars and the degree of protection conferred against smallpox. Indeed, it so happens in the table that the death rate among the patients having but one "good" mark is a little lower than among those having 4 or more "good" marks. There is no doubt that vaccine, characterized by a single typical vesicle, destroys in the individual all susceptibility to smallpox, and it would be impossible for multiple vesicles to do more than that. As a safeguard against failure, however, or when using long-humanized virus, it is advisable to make several insertions; but I must repeat that it is my positive conviction that the quality of vaccine lymph has far more to do with securing efficient vaccination than have multiple insertions.

In the next table is illustrated, first, the efficacy of recent vaccination, as performed in infancy, and, secondly, the gradual loss of vaccine protection as the individual grows older.

TABLE 8.—*Showing the cases classified as to age periods of the patients, and also as to their vaccine condition in each period.*

| Ages.                         | Ad-<br>mitted. | Died. | Per cent<br>of<br>deaths. |
|-------------------------------|----------------|-------|---------------------------|
| Under 1 year:                 |                |       |                           |
| Unvaccinated .....            | 78             | 57    | 73.07                     |
| Vaccinated .....              | 2              |       |                           |
| 1 to 7 years:                 |                |       |                           |
| Unvaccinated .....            | 404            | 208   | 51.48                     |
| Vaccinated in infancy—        |                |       |                           |
| Good mark .....               | 10             |       |                           |
| Fair mark .....               | 10             | 1     | 10                        |
| Poor mark .....               | 15             | 1     | 6.66                      |
| Total number vaccinated ..... | 35             | 2     | 5.70                      |
| 7 to 14 years:                |                |       |                           |
| Unvaccinated .....            | 222            | 71    | 31.98                     |
| Vaccinated in infancy—        |                |       |                           |
| Good mark .....               | 55             | 2     | 3.63                      |
| Fair mark .....               | 23             | 2     | 8.69                      |
| Poor mark .....               | 59             | 9     | 15.25                     |
| Total number vaccinated ..... | 137            | 13    | 9.48                      |
| 14 years and upward:          |                |       |                           |
| Unvaccinated .....            | 1,038          | 681   | 65.60                     |
| Vaccinated in infancy—        |                |       |                           |
| Good mark .....               | 1,344          | 122   | 9.07                      |
| Fair mark .....               | 629            | 93    | 14.78                     |
| Poor mark .....               | 994            | 280   | 28.16                     |
| Total number vaccinated ..... | 2,967          | 495   | 16.68                     |

It can not be questioned that in a large city like Philadelphia, where gratuitous vaccination is provided for the poor and improvident class of the community, there must be a very much larger number of children under 1 year old vaccinated than unvaccinated, and yet it is seen by the table that 78 of the latter were admitted to the hospital and only 2 of the former. The unvaccinated perished in the proportion of 73.07 per cent, while both of the vaccinated cases of course recovered. One of the vaccinated children was 11 months old, had been vaccinated two months previously, showed a good cicatrix, had varioloid in an exceedingly mild form, the eruption consisting of only six small vesicles, and the child was at no time ill. The other vaccinated case had the disease so indistinctly marked that following the diagnosis of varioloid, as recorded in the record book, I find a mark of interrogation. These facts show that smallpox among unvaccinated children under 1 year old is very common and fatal, and that among vaccinated children at this age it is very rare, and when it occurs at all it is no more to be feared, so far as danger to life is concerned, than ordinary vaccina.

In children between the ages of 1 and 7 years smallpox is, of course, very common among the unvaccinated, and occasionally it is seen in a very mild form among the vaccinated; but death never results where there is evidence of thorough vaccination, except occasionally from some complication. It is seen in the table that one death occurred under the head of "fair" vaccine mark. In this case the child was about 1 year old, a foundling, badly nourished, having disordered digestion, and was very feeble. The eruption consisted of only a very few small vesicles. Death resulted from sheer debility. Very little need be said of those classified under the head of "poor" vaccine scars, as the vaccination in all such cases was either imperfect or spurious. In the next age period, 7 to 14 years, it is worthy of note that the death rate among the unvaccinated cases is very much lower than at any of the other age periods. Possibly the explanation of this is that the

recuperative powers of life are most active at that age, or that some of the depressing habits common in later life, such as intemperance and the like, have not yet been formed. At this period of life post-vaccinal cases of smallpox increase considerably, and occasionally death occurs from the disease, even after quite thorough infantile vaccination. These facts clearly indicate that the vaccination of infancy is apt to lose at this period more or less of its protective power.

The last age period noted in the table, 14 years and upward, illustrates, in the first place, how large is the number of youths and adults who have never enjoyed the prophylactic power of vaccination. Among this class, too, the death rate is seen to be considerably higher than that of the corresponding class in either of the two preceding age periods. The table also proves in a very indubitable manner, by the great increase of post-vaccinal cases of smallpox at this age period, that vaccination in infancy can not be depended upon to confer protection against the disease in the later life of the individual. There are, therefore, two important facts prominently brought forward in this table: First, that recent vaccination confers absolute, or almost absolute, protection against smallpox; and, secondly, that when vaccination has been performed in infancy revaccination is required at, if not before, the age of puberty.

My experience leads me to place implicit confidence in the efficacy of revaccination, although the statistics presented in the following table are somewhat vague and indefinite and do not fully nor clearly demonstrate the real merits of the measure. The table simply contains the relevant data as obtained from the patients who claimed to have been vaccinated in infancy and subsequently revaccinated, together with the general results.

TABLE 9.—*Showing the cases occurring in patients after alleged revaccination.*

| No. | Age.   | Character of marks from vaccination in infancy. | Character of marks from the alleged revaccination. | Length of time since the alleged revaccination. | Disease.           | Result.  | Num-ber of days in hos-pital. | Remarks.                                                                                                                    |
|-----|--------|-------------------------------------------------|----------------------------------------------------|-------------------------------------------------|--------------------|----------|-------------------------------|-----------------------------------------------------------------------------------------------------------------------------|

| 78 | Fair       | Poor                     | Poor                     | 17 yrs       | do       | do       | 27 |

In tabulating the cases represented in the above table I have been obliged to accept the statements of the patients; first, as to the fact of revaccination; and secondly, as to the time when it was performed. Their testimony as to whether or not it was successful I have found very unreliable. To use their own language, they often said "It took a little," or "The arm was very sore," and frequently they did not remember whether it "took" at all, but would point to a mark which they said they had always believed was the result of revaccination. Not unfrequently marks were pointed out as the result of revaccination which were an exact counterpart of one or more other marks present on the arm, and which were known to have resulted from the primary vaccination. It is evident, therefore, that it would be very difficult to say how many of the cases recorded in the table should be regarded as authentic examples of smallpox occurring after successful revaccination. Some, I think, should be so regarded.

The more positive evidence of the efficacy of revaccination is to be found in the fact that persons recently revaccinated with effect do not take smallpox when freely exposed to the infection. During my service of twenty-three years no resident physician of the hospital, no nurse, laundress, cook, nor any other employé who was properly revaccinated before entering on duty has taken smallpox. Perhaps I should except a female nurse, who was revaccinated on the first day of her residence in the hospital, with almost typical result. In the course of about two weeks I noticed on the forehead of this nurse, near the edge of her hair, one or two variolous vesicles, which were preceded by but little if any febrile disturbance. At any rate, she was at no time disabled from performing her usual duties.

What vaccination has done for these employés, whose duties have necessarily brought them in the closest possible contact with the infection of smallpox, it will do for any or all who fully avail themselves of its protective influence. I am firmly of the opinion that if all persons were properly vaccinated in infancy, and again at the age of puberty, Jenner's prediction as to the power of this agent to extirpate smallpox from the globe would soon be realized.

In the following and last table which I shall present is contained the principal data at hand in regard to the cases or alleged cases of second attacks of smallpox. There is found in it, also, the same element of uncertainty as to the authenticity of many of the cases as existed in the preceding table, though perhaps to a less degree, and this uncertainty is owing to the same cause, namely, the unreliability of evidence furnished by the patients.

TABLE X.—Showing the alleged cases of second attacks of smallpox.

| No. | Pres-ent age of pa-tient. | Age at which the alleged pre-vious attack occurred. | Whether or not vacci-nated prior to the alleged previous at-tack. | Character of the vac-cine mark. | Extent of pit-ting.     | Type of present attack. | Result.  | Remarks.                                                                                                                           |
|-----|---------------------------|-----------------------------------------------------|-------------------------------------------------------------------|---------------------------------|-------------------------|-------------------------|----------|------------------------------------------------------------------------------------------------------------------------------------|
| 1   | Years, 35                 | 6 years                                             | Not vacci-nated.                                                  | -----                           | Very little             | Greatly modified        | Recovery | Was confined to bed only during the initial stage.                                                                                 |

| 45  | 50                                   | 2 weeks                                                          | Vaccinated                                                                         |                                        | No pitting            | Modified                   | do       |                                                                                                                                                                            |

It is certain that very many of the cases recorded in the foregoing table should not be regarded as true cases of recurrent smallpox. For instance, where it is seen that a smallpox patient has never been vaccinated, shows little or no pitting, and is suffering from an unmodified form of the disease, it is more than probable that there has been no previous attack. Slight pitting, when present, is not necessarily proof of such an attack having existed; for the pitting may have resulted from chicken pox, which disease, I well know, is often mistaken for smallpox. So also all those cases having a history of thorough vaccination in infancy, if characteristic pitting of the alleged previous attack is absent, should be regarded as very doubtful cases of recurrent smallpox. It would be very exceptional, indeed, for a person first to take vaccina, then smallpox, and subsequently a second attack of the disease. There is no doubt that a few of the cases recorded in the table should be regarded as genuine second attacks of smallpox, but in most such cases the disease was exceedingly mild—so mild, indeed, in some instances as scarcely to be recognizable. I have never yet seen an unmodified, or even a severe, case of smallpox occur in a person who was deeply and characteristically pitted from a previous attack. Such cases I know may be found on record, but it has not been my fortune to meet with them. I might say, furthermore, that during my many years of service no person has been admitted to the hospital twice suffering from any form of the variolous disease. In view of all these facts I can not but believe that second attacks of smallpox are much rarer than is generally supposed.

---

#### DISCUSSION.

Dr. VALENTINE. The paper we have just listened to with so much pleasure, indorsed and corroborated by the statistics Dr. Welch offers, is most opportune. Particularly now is this the case, when so much agitation is waged against vaccination. Such comments and demonstrations are needed especially to combat the silly anti-Jennerism now so prevalent in Germany, where, not three months ago, a petition was sent to the Government praying for the abolition of the "Moloch of vaccination." The records of this congress, which will go into print, should certainly give this paper due space, and I hope it will reach the general public, lest it be misled by the clamor which may soon cross the ocean. Let the author's valuable paper receive the critical indorsement of this section and of the congress in general, so that by its influence Jenner's prediction may be fully verified. The mission of the congress for the good of the public will then be thoroughly done, even if it accomplishes nothing else.

Dr. LOUIS A. DUHRING, of Philadelphia. I congratulate the author and the congress upon the excellent paper, which introduced so many striking tables, carrying conviction with them, concerning the great protective value of vaccination. It is a boon to humanity which the world does not yet sufficiently appreciate, as shown by the unwarranted opposition still put forth by the laity in Great Britain and Germany at the present day. Such statistics, properly presented, must go far to convince the people of all countries of the great protection which vaccination confers, and it is to be hoped such information may reach the laity everywhere, as well as the profession. I would ask the reader of the paper if he had made any special observations relating to the amount of eruption as bearing on the disease as a whole, and especially as to the mortality.

Dr. RAVOGLI. Dr. Welch deserves to be highly complimented for his interesting paper. Before the power of the ciphers nobody can make many remarks; the ciphers speak for themselves. I fortunately never had occasion to see many cases of smallpox, as in the city of Cincinnati, since 1881, we were so lucky as not to have had a single case of the disease. However, in my early experience I had occa-

sion to see many cases of smallpox in the hospital of Santo Spirito, in Rome, Italy, where four large halls were kept purposely for this disease. At the time of the government of the priests no compulsory vaccination had been established, and so the low, ignorant class was not vaccinated, and those halls were almost constantly filled with patients affected with variola. After the establishment of the Italian Government compulsory vaccination was ordered, and, gradually increasing the vaccination among the people, the number of the cases of smallpox diminished to such an extent that the smallpox halls were often kept closed. In the epidemic which affected Cincinnati in 1881 I saw several patients not only vaccinated, but also revaccinated a short time before being attacked, with smallpox which was of a malignant nature. After the third or fourth day petechiæ appeared on the body, with symptoms of collapse, and the patient died. Anyhow, I agree thoroughly with the essayist in the value of the vaccination as protection against smallpox. I am an advocate of revaccination, which I believe is a necessity. If I may make a remark on the paper of the essayist, I find that revaccination is not taken into consideration. I find that every pupil going to the high schools, the soldiers taking service in the Army, the prisoners, all who come under the rule of the Government, ought to be carefully revaccinated and the result watched, so as to obtain good marks from the efflorescence.

Dr. RAKE. I hope Dr. Welch's paper will become known all over the world. It comes at a most appropriate time. There is a strong antivaccination party in Great Britain, and much pressure is being brought to bear on the Government to relax the penalties for breach of vaccination laws. In Trinidad, where vaccination is being rigorously carried out, there has been no case of smallpox since 1871, when there was a severe epidemic, and the mortality was so high that compulsory vaccination was made legal. Though smallpox frequently occurs in the other West Indian Islands, Trinidad has been quite free since 1871.

Dr. Cobb complimented the writer on his learned and conclusive address.

Dr. W. S. GOTTHEIL. I should like to ask Dr. Welch if he can, from his very large and exceptional experience, answer two practical and important questions: (1) Is the presence of a large, well-marked scar a guaranty against infection? (2) Does a failure of revaccination demonstrate unsusceptibility to the variola poison?

Dr. WELCH. Very much indeed do I appreciate the complimentary remarks on my paper. In regard to the question of the quantity of the eruption increasing the danger in smallpox; there is no doubt that where the eruption is most intensely confluent the danger to life is greatest. Discrete smallpox is not very dangerous. Recovery from the hæmorrhagic or malignant type of the disease is very rare indeed. In reply to the question as to whether a typical vaccine scar indicates that the individual is protected against both smallpox and revaccination, I would say that I have frequently seen persons bearing such marks suffer from smallpox, and even perish from the disease. Of course, if susceptible to smallpox, they would have taken the vaccine disease if revaccination had been performed. Failure to succeed with revaccination does not necessarily show that the individual is immune; it may be due to inert virus. I think that susceptibility to smallpox, destroyed by infantile vaccination, returns later in life in the great majority of persons.

## PRIMARY DYSTROPHIES OF THE SKIN; WITH AN INTRODUCTION ON THE NOSOLOGY OF DISEASES OF THE SKIN, AND AN APPENDIX ON SECONDARY DYSTROPHIES.

By EDWARD PREBLE, M. D., of Cleveland, Ohio.

All colleagues are agreed that our present modes of grouping skin affections are far from satisfactory; and certain writers, in despair of attaining a good working classification, have taken refuge in a mere alphabetical arrangement of the subject-matter. The vast number and variety of nosological systems have glutted our science with names and synonyms, and have produced a reaction in the shape of nosological nihilism. Now, for this state of affairs there is no valid excuse. The truth lies herein, that in the present state of our science the dermatoses are divisible into two families, namely, those which admit of grouping upon a natural basis, and those which are properly unclassifiable. Numerous writers (I regret that I am unable to give each his due) have during the past few years supported these views in a fragmentary or incidental manner. The present writer has on several occasions attempted to present this doctrine systematically, and especially in a paper read before the 1892 session of the American Medical Association. In this paper attention was called to the fact that our notion of a disease is derived from the sum of its attributes; that is to say, its etiology, locality, pathology, evolution and course, termination, symptomatology, reaction to treatment, etc., and that diseases which have a majority of attributes in common constitute a natural family of dermatoses. It follows, therefore, that when these attributes are known as facts of science, the diseases in question are amenable to a classification which ought to be acceptable to all writers; and that when a majority of attributes are yet in doubt any attempt at classification will be futile, and therefore with diseases of this sort we are quite justified in falling back upon a mere dictionary arrangement of the subject-matter.

There seems to be among many recent writers a consensus of opinion that certain dermatoses are sufficiently understood to admit of a classification which ought to be as nearly perfect and permanent as any in use in any branch of contemporary science. These dermatoses include the following natural groups: Primary dystrophies, acute dermatitides, cutaneous suppurations, poison wounds, occupation dermatoses, parasitic diseases, and finally the infective granulomata, which are due to long-lived microorganisms. At the same time the best authorities are constrained to admit that we are as yet ignorant of the chief attributes and nature of such dermatoses as eczema, psoriasis, lichen planus, prurigo, pityriasis rubra, dysidrosis, lupus erythematosus, etc. The causes are utterly unknown, and while we may have some conception of anatomical seat and pathology, other attributes appear under such protean phases that the inductive method can not be satisfactorily applied.

We have selected the first natural group above mentioned, viz., primary dystrophies, as an example of dermatoses which are perfectly classifiable, and give further on an analysis of attributes. But before we undertake this task we wish to say a word further regarding unclassifiable diseases of the skin. Conditions such as eczema, psoriasis, and lichen planus are eminently protean in form and therein resemble the cutaneous lesions of syphilis, lepra, and tubercle, differing, however, markedly in this, that the former diseases are peculiar to the skin (with the exception of a few mucosæ). These dermatoses are of course due either to local or systemic causes, or to both. If due to the former, there must surely be some element of dystrophy in the skin, which serves as a predisposition and upon which slight and varied irritants are capable of producing a chronic diseased state. That such a thing is possible in dermatology is best shown in the case of late syphilides,

where in a skin which has suffered in early syphilis as, for example, the palm, moderate mechanical irritation, such as come from the tailors' shears or other tool, may cause specific lesions corresponding exactly to the area of local irritation. Other diseases, such as acne and lupus erythematosus, may illustrate the coöperation of irritants and a dystrophic skin in their production. The science of the future will determine the nature of the soil in which these dermatoses are able to flourish, and conversely the reaction of the markedly dystrophic skin to ordinary irritants. If, however, these unclassified dermatoses are due to systemic causes, then we should be able to detect collateral lesions in other organs of the body. It is everyday experience that an eczema, for example, will appear, exacerbate, spread, relapse, recrudescence, etc., exactly as does a rhinitis, a bronchitis, or an enteritis, and under precisely the same circumstances, as exposure, indigestion, etc.; so that in certain cases we may speak, figuratively of course, of a general catarrhal disposition which elects now one organ, now another, for its expression. Or again, an eczema will certainly appear in the same people and under the same circumstances as does a gouty or rheumatic attack in parts of the locomotor system. I have often thought in a given case: Here is a man of a certain age and temperament, a high liver, taking little exercise, and having a family history of gout, with his first attack of eczema; logically, he should have had instead a paroxysm of gout, and his eczema gets well under the antilithic regimen. The clinical evidence is complete that he has had his gout in the skin. The science of the future will isolate the irritant in these cases and the path of its action on the skin. We have said enough to show that before we can classify such dermatoses as eczema further research into both the predisponent soil, and the nature and path of various irritants, from within and without, will be imperative. We now pass on to a study of primary dystrophies.

#### ABSTRACT OF A PAPER ON PRIMARY DYSTROPHIES OF THE SKIN.<sup>1</sup>

*Nosology.*—Primary dystrophies form a true family of dermatoses, distinguished by simple redundancy or defect of the anatomical elements of the skin, or by habitual functional perversity, with a purely physiological type of (respectively) development or involvement; and (negatively) by the absence of all of the exciting causes and pathological phenomena of other dermatoses. Redundancies are divisible into simple, diffuse hypertrophies, naevi, and benign tumors. The hypertrophies are limited to a single superficial tissue, with regional predilection, diffuse area, and exquisitely hereditary transmissibility *per se*; and comprise various diffuse forms of hyperkeratosis, hypertrichosis, hyperchromia, telangiectasis, and follicular redundancy. Naevi are sharply circumscribed, often composite, redundancies of the superficial tissues, having no regional predilection, and varying greatly in size, shape, number, location, and composition. They comprise the various so-called moles, and certain sebaceous and corneous formations. Benign tumors are multiple, disseminate redundancies originating in the deeper cutaneous layers, and comprise the dermoids, atheromata, and tumors of the connective tissue series. Occasionally large, isolated forms occur. Defects consist of absent, tardy, or partial development, premature involution of the senile type, and pathological involution of certain anatomical elements of the skin. They include certain forms of atrophoderma, achroma, atrichia, keratolysis, etc., and are often strikingly hereditary. Functional instead of structural perversity is seen in certain forms of hyperelasticity, in exaggerated skin-reflex, in the so-called flush patch and chilblain circulation, and in the production of horny sebum and oily sweat.

<sup>1</sup>The notes of which this is an abstract are not in shape for publication, besides being too voluminous for a short paper.

*Etiology.*—Heredity *per se* is present so often and so exquisitely that with negative history we may often assume either imperfect data or atavism; and when heredity *per se* is absent, there is often evidence of a general inherited disposition to dystrophy of the skin. Heredity must mean ultimately either atavistic reversion, or the transmitted results of miscegenation and inbreeding. Dystrophies in the site of the original lines of fusion presuppose either foetal arrest of development or the inclusion of latent embryonal remnants.

*Pathology.*—Redundancy and defect are but phases of a common dystrophy, and often coëxist. Any distinction between diffuse hypertrophy and homologous tumor-formation is artificial. The life history of primary dystrophies has its parallel in the development or involution, respectively, of the temporary physiological organs (hair, teeth, thymus, mammæ, etc.).

*Course.*—Redundancies progress slowly to a maximum, and then tend to remain stationary, with occasional spontaneous involution. Defects are likewise progressive, with occasional arrest and, rarely, regeneration.

*Diagnosis.*—Primary dystrophies require differentiation from forms secondary to local mischief, or to central influence.

*Complications.*—Primary dystrophies tend to coëxist in the same skin, often in great variety; and high degrees are often associated with dystrophy elsewhere in the body.

*Sequelæ.*—Dystrophies are elements of the greatest significance as predisponents to the establishment and chronicity of skin diseases.

*Treatment.*—The indications are to produce arrest, and, respectively, involution or regeneration. This is possible only in a slight degree, although many redundancies may be removed outright by surgical procedure.

#### APPENDIX ON SECONDARY DYSTROPHIES.

Probably no one, after due deliberation, will question the propriety of making the dystrophies a separate family of dermatoses. As our abstract has discussed only the primary forms, a few words may be added in regard to secondary dystrophies. A number of redundancies and defects may result from local disease or injury, and these are therefore termed secondary dystrophies of local origin. Some of these are analogous to the primary forms, such as hyperchromia, while other forms, such as diffuse hypertrophy of the derma, are probably never primary, but always due to an increased nutrition of the parts, depending on local or central causes. So the interstitial atrophy of the derma which follows certain diseases has no parallel in the primary forms of defect. A still wider departure is present in cicatrices, although they have a primary analogue in spontaneous keloid. Turning now to secondary dystrophies of internal origin, we find a still greater number and variety in the species. Certain redundancies and defects appear to be due to vascular lesion, particularly in the lymphatic system, as seen in elephantiasis of all kinds. Another large group is of distinctly nervous origin, due to lesion of the various members of the nervous system, central or peripheral. The term dystrophy of the skin was in fact originally restricted to the so-called trophic affections of the nerves which supply the skin. Secondary dystrophies of nervous origin appear to be defects and never redundancies. Here belong the cutaneous lesions of wounded nerves, of lepra nervorum, ataxia, syringo myelia, etc. A third and extremely interesting group, and one newly studied, is the secondary dystrophy due to anomalies of the ductless and reproductive glands. The lesions of the skin are often associated with collateral change elsewhere in the body. The glands referred to are the thyroid, thymus, hypophysis cerebri, and possibly the adrenals, and the ovary and testis. It may be shown eventually that lesions of the spleen, bone marrow, etc., are capable of modifying the nutrition of the skin. Our knowledge of the dystrophies of glandular origin is yet in its

infancy, and we therefore forbear to enumerate special affections beyond a mere allusion to myxedema, acromegaly, and certain dystrophies of the pigmentary and pileous systems.

There still remain certain purely artificial conditions which resemble, in some respects, the natural dystrophies, and should therefore be considered here. We refer to the various forms of foreign coloring matter introduced into the skin, intentionally or accidentally, from without or within. Here belong all kinds of tattooing, powder and coal marks, and all dyes and stains, together with argyria and analogous discoloration from within.

Briefly recapitulated, dystrophies are primary or secondary to local mischief, and to vascular, nervous, or glandular influences. Primary dystrophies are either transmitted by descent or due to errors of development. With dystrophies are placed for convenience certain artificial conditions of the skin of a chromatogenous character.

## LAS ENFERMEDADES CARBUNCULOSAS Y SU ESPECÍFICO: EL AMONIACO.<sup>1</sup>

Por LEONIDAS AVENDAÑO,

*Doctor en Medicina, Catedrático de la Facultad de Medicina de Lima, y Redactor en Jefe de La Crónica Médica de Lima.*

### I.

Las enfermedades carbunculosas forman un grupo de afecciones microbianas originarias del ganado vacuno y lanar y trasmisibles al hombre por contagio, realizándose este último por un microorganismo especial: la *bacteridia carbunculosa* (Davaine) ó el *bacillus anthracis* (Cohn), están caracterizadas por una tendencia marcada á la mortificación de los tejidos ó gangrena, que les ha valido en todo tiempo el nombre de carbón ó carbúnculo, acompañada de un estado general más ó menos grave.

El bacilo específico es un ser aerobio que genera la enfermedad con su sintomatología característica por doble acción: mecánica y química. Mecánica, multiplicándose de un modo prodigioso á tal punto que una bacteridia genera en setenta y cuatro horas 137.219'353.312, lo que origina obstrucción de los pequeños vasos sanguíneos y la asfixia consiguiente de los tejidos, químicamente privando á los glóbulos sanguíneos del oxígeno que necesitan para su subsistencia y secretando, una vez vencidos los hematias, una tomaína que produce los síntomas propios de la infección.

Las diversas experiencias de laboratorio practicadas para conocer la acción de los diversos agentes químicos sobre el bacilo del carbúnculo y sus esporos, pueden reasumirse con el Profesor Perroncito, de Turín, en las siguientes conclusiones: Mantienen su actividad completa los esporos durante una hora, á 90 y 95°, y por diez minutos, de 99.5 á 100.4. Además el virus resiste mes y medio á la acción de la glicerina, media hora al alcohol absoluto, veinte minutos al cloruro de zinc, veintiuna horas á la solución saturada de ácido salicílico;  $\frac{1}{300}$  de ácido, de diecisiete horas á siete días, cuatro horas; al amoniaco débil, veintiuna horas, y al fuerte, media hora; doce á cincuenticinco minutos á la solución acuosa de ácido fénico al 5 por ciento. Los esporos murieron: en ácido nítrico al 20 por ciento, á las veintiuna horas; de 105° á 134°, á los cincuentiocho minutos; y, de 120° á

<sup>1</sup> El presente trabajo fué leído por su autor en una conferencia habida en la sociedad médica "Unión Fernandina," el 28 de octubre de 1885. Para enviarlo al Congreso Médico Pan-Americano se han suprimido los párrafos de poca importancia, agregándole los datos nuevos adquiridos hasta la fecha.

143°, en once minutos; de 90° á 91° en un tubo de vidrio cerrado á la lámpara, una hora y nueve minutos. Los bacterios fueron inactivos y murieron: de 48° á 50° por 25' á 30'; en soluciones fenicadas, al 1, 2, 3, 4 y 5 por ciento. Los esporos resistieron: al alcohol absoluto ciento veinticuatro días; ácido fénico, 1 por ciento, sesentiu días; al 5 por ciento, veintiseis días; sublimado al  $\frac{1}{3000}$ , tres días, dieciocho horas;  $\frac{1}{10000}$  por ciento, cuarentidos días; el agua hirviendo con  $\frac{1}{3}$  de virus por  $\frac{2}{3}$  de agua los alteró. El bacilo murió: en sublimado al  $\frac{1}{200}$  á los veinte minutos; al  $\frac{1}{400}$  á los treinticinco minutos; al  $\frac{1}{1000}$  á las dos horas; al  $\frac{1}{6000}$  á los ochentisiete días. Á las temperaturas de 80° á 107°, durante ocho minutos, y después de 107° á 115°, por seis minutos. Después de 12' entre 80° á 90°, y 21' entre 80° y 90°, 5' entre 91° y 93°, y 6' entre 92° y 94°. Los bacterios murieron: en  $\frac{1}{300}$  de ácido tónico, á los cinco minutos; y á los diez en alcohol absoluto.

Citaremos también, tratando de las sustancias que aniquilan la vitalidad del bacillus anthracis, los trabajos de Davaine, en lo que se refieren á la acción del iodo y del sublimado, de los que resulta que, para neutralizar la acción del bacilo se requiere una solución de  $\frac{1}{170000}$  de iodo y  $\frac{1}{150000}$  de sublimado, como límite extremo.

Pero, haré presente que estas observaciones de laboratorio no están muy acordes con las enseñanzas de la clínica, y que las dosis necesarias de los diversos antisépticos mencionados, quizás si serían dañinas para el organismo del hombre; esto, sin tener en cuenta las transformaciones que se realizan en el seno de la economía. Como prueba de este aserto, dice Colin lo siguiente: "El iodo hace maravillas en los vidrios de reactivos, en presencia de una milésima ó millonésima de gota; pero, según parece, en el organismo no obra de igual manera."

No me ocupo del estudio de las múltiples causas que favorecen el desarrollo y contagio de las enfermedades carbunculosas, por ser muy conocido y poco necesario para el objeto que me propongo. Igual consideración hago en lo que se refiere á la sintomatología, marcha y pronóstico de estas afecciones.

## II.

Las formas bajo las que se presentan las enfermedades carbunculosas en el hombre son: la pústula maligna, el edema maligno, y la fiebre carbunculosa. Las tres reconocen la misma causa, la penetración del bacillus anthracis en la economía; su diversidad es debida á los distintos efectos que ocasiona la bacteridia según la vía por la que se introduce en el organismo.

Pero antes de pasar adelante debo dejar definitivamente sentado que la bacteridia es un ser aerobio que necesita oxígeno para su subsistencia, y que su mejor medio de cultivo en el organismo es la sangre; de modo que cualquiera que sea la vía por la que penetra procura llegar hasta el torrente circulatorio, en donde encuentra al glóbulo sanguíneo, también ávido de oxígeno, y se establece entre ellos una lucha por la existencia; cuando el organismo posee suficientes elementos de vitalidad vence el hematia, se aniquila la bacteridia sin reproducirse y se restablece el estado normal—es la fuerza medicatriz de los autores antiguos, que explica la curación espontánea de algunos casos de enfermedades carbunculosas—pero, por el contrario, cuando el organismo se encuentra debilitado por una causa cualquiera, ó que el ataque ha sido muy violento, entonces el bacillus anthracis predomina, repulula y se realiza la infección de la economía.

La localización del bacillus anthracis en la superficie cutánea da margen á la pústula maligna.

La bacteridia se insinúa por los intersticios de los tejidos de la piel, previa su solución de continuidad, priva á estos del oxígeno que contienen, los gangrena, siendo esta la causa del núcleo negro é indurado que forma el centro de la pústula; después gana los linfáticos para llegar por ellos á los ganglios, produciendo el edema inflamatorio que rodea á la pústula y el infarto de los ganglios tributarios

de los linfáticos del sitio donde radica la afección; del sistema linfático pasa al torrente circulatorio, donde puede aniquilarse ó reproducirse, según hemos visto antes, produciéndose la infección en el segundo caso, la que siempre es tardía por el largo trayecto que tiene que recorrer la bacteridia para llegar á su mejor medio de cultivo: la sangre.

Cuando la penetración de la bacteridia se realiza por una mucosa próxima á las aberturas naturales, ó por una solución de continuidad profunda de la piel, se origina el edema maligno. En este caso el germen se encuentra en un medio en que la circulación es más activa, su acceso al torrente circulatorio es más fácil, y sin ocasionar la mortificación primitiva de los tejidos, los ataca de una manera violenta, engendra un edema inflamatorio intenso é infecciona al organismo con mayor rapidez que en el caso anterior.

Finalmente el organismo puede ser atacado por la mucosa de los órganos respiratorios ó digestivos, modo de penetración que puede asimilarse á la inoculación directa por el torrente circulatorio, pues es sabido la rapidez con que las diversas sustancias introducidas por estas vías pasan directamente á la sangre. En este caso se presenta la fiebre carbunculosa; se realiza directamente la infección de la economía sin lesión local, el bacillus anthracis ha encontrado pocos obstáculos para difundirse rápidamente por la economía y el ataque al organismo es así más enérgico y seguro.

Se comprende fácilmente, según esto, la gravedad relativa de estas tres formas. La pústula maligna ocupa el último lugar en la escala; su curación espontánea, lo mismo que la de las otras formas, no es rara, y la lentitud de su marcha permite destruir al causante del mal, antes que se apodere por completo del organismo. Sigue después el edema maligno, en el que la marcha ya algo rápida del bacillus anthracis, obliga á combatirlo con más energía. Por último, en la fiebre carbunculosa, el ataque al organismo es rápido, violento; la bacteridia penetra directamente á la sangre; de consiguiente es necesario batirla en el mismo medio en que mejor se desarrolla: en el líquido nutritivo por excelencia. Felizmente esta última forma, algo frecuente en los animales, es algo rara en el hombre, á tal punto que algunos autores dudan de su existencia; pero existen hechos positivos que demuestran la realidad de ella.

### III.

Prescindiendo de las diversas medicaciones más ó menos inútiles que se han empleado contra la pústula y el edema malignos, que son, como ya lo he dicho, las dos formas más comunes de las enfermedades carbunculosas en el hombre, el tratamiento clásico de estas afecciones ha sido, y es, la insición y la cauterización del sitio primitivo del mal. En los casos en que la pústula es muy extensa, se excisan los colgajos que resultan de la insición, y en la solución de continuidad que resulta se aplica directamente el cáustico. El cauterio actual es el que ha gozado de más boga, y de los cáusticos potenciales se han empleado casi todos, hasta el nitrato de plata (Gautheret, Tesis de Paris, 1859), cuyo débil poder es de todos conocido; pero el que ha merecido la preferencia, y es indicado por todos los autores en primera línea, es el bicloruro de mercurio, sal bastante corrosiva y que hoy ocupa uno de los primeros lugares en la medicación antiséptica. La mayoría de nuestros prácticos ha usado siempre el protocloruro de antimonio (manteca de antimonio) cuerpo que á su excesivo poder reúne la singular ventaja de ejercer una acción especial sobre los venenos de origen séptico, los virus de origen animal como se les llamaba antes; y es quizá por esto que las pústulas malignas rara vez llegan entre nosotros á su período de infección.

Esta medicación instituida en los tiempos en que la palabra virus carecía de significación precisa, es sin embargo racional, y se encuentra en conformidad con los descubrimientos modernos. Antes del establecimiento definitivo de la teoría

parasitaria, se conocían perfectamente los efectos de los virus, pero no podía encontrarse la explicación racional de ellos; á los virus se les concedía una acción oculta, invisible, impalpable, en una palabra, incomprensible; necesitaban, sí para ejercer su acción, una vía favorable para introducirse á la economía.

La observación atenta había demostrado que el virus carbunculoso ejerce primero su acción local antes de penetrar al interior del organismo, de consiguiente lo lógico, lo racional es tratar de impedir esa penetración; y el medio más eficaz para ello destruirlo antes que ésta se realizara. Á ese fin obedece el empleo de los cáusticos, que no puede menos que aprobarse, hoy que se sabe que la bacteridia carbunculosa permanece por algún tiempo en las mallas de la piel antes de introducirse al torrente circulatorio é inficionar al organismo. Acepto, pues, la cauterización primitiva del tumor, pero con ciertas reservas respecto á su manual operatorio y á la sustancia que debe emplearse, reservas que expondré al final de este incorrecto trabajo.

Fuera de la cauterización, no se ha empleado antes ningún agente capaz de atacar directamente al germen de la enfermedad en la profundidad de los tejidos; pues los demás medicamentos usados, lo son únicamente para llenar las indicaciones que sucesivamente se presentan, evacuantes al principio de la afección, atemperantes para moderar la elevación térmica, tónicos para levantar ó sostener las fuerzas del organismo, tónicos diversos, para favorecer la cicatrización de las heridas resultadas de la aplicación del cáustico, etc.

Cuando Davaine adquirió el pleno convencimiento de que la bacteridia carbunculosa era el agente exclusivo de la producción y trasmisión de las enfermedades carbunculosas, tanto en los animales como en el hombre—convencimiento que fué robustecido por las ulteriores experiencias de Pasteur, Jobert, Koch, Tous-saint, Duclaux y otros; y después de haber encontrado el medio de atenuar la virulencia del bacilo, de modo de convertirlo en vacuna preservativa, extendió el campo de sus experiencias á la investigación de los agentes capaces de aniquilar la vitalidad de la bacteridia. En efecto notó que neutralizando la sangre de los animales atacados de carbúnculo, por soluciones de diluídas de iodo, de ácido fénico ó de amoniaco é inoculándola después á otros animales, la enfermedad no se reproducía en estos últimos; quedando así demostrado que dicho líquido se había vuelto inactivo, en una palabra, las bacteridias que contenía habían dejado de existir.

Estas esperiencias hechas á principios del decenio pasado, y oportunamente comunicadas á la Academia de Medicina de Paris, hicieron pensar á algunos prácticos si no sería posible aplicarlos como medio curativo tanto en el hombre como en los animales; pues si las sustancias antes mencionadas, consideradas, y con justicia, como antivirulentas, aniquilaban el germen de la enfermedad en la sangre extraída de los animales enfermos lo mismo que en los diversos medios de cultura, su acción tenía que ser la misma en el organismo del hombre ó de los animales presa de la bacteridia — habiendo sido Declat el primero que empleó el ácido fénico al interior para combatir el carbúnculo en los animales. A éste siguieron muchos que emplearon el ácido fénico y el iodo, convenientemente diluidos, para destruir el microbio, administrándolos en algunos casos por las vías digestivas y en todos en inyecciones hipodérmicas en el sitio del edema inflamatorio. Así nació el método que se llamó de las “inyecciones neutralizantes antivirulentas en el tratamiento de las enfermedades carbunculosas.”

Los casos tratados de este modo que he podido encontrar en los documentos que he consultado sobre esta cuestión son los siguientes: Un edema maligno de los párpados, curado por los Dres. Bienfait y Gentilhome (1872) empleando las inyecciones de licor de Labarraque. Uno de pústula maligna, curado por los Dres. Jaillot y Collot (1873) por medio de inyecciones iodo-ioduradas. Un edema maligno de la cara, curado por el Dr. Rainfert (1873) por inyecciones de ácido

fénico. Una pústula maligna, tratada por el Dr. Verdureau (1874) por las inyecciones de ácido fénico. Una pústula maligna, tratada por el Dr. Rainvert (1874) por las inyecciones de iodo-iodurado. Un edema maligno de la pierna, curado por el Dr. F. Meplain (1875) por las inyecciones de ácido fénico. Un caso observado por el Dr. Baladon (1878) con la solución iodo-iodurada. Una pústula maligna, tratada por el Dr. Remy y curada con la solución iodo-iodurada (1878). Un caso del mismo autor y en el mismo año por el ácido fénico. Cuatro casos del Dr. Chipault (1880) curados por las inyecciones iodo-ioduradas. Dos casos del Dr. Rigault, curadas también por la solución de iodo (1878). Siete casos del Dr. René Raimbert (1880) tratados por el ácido fénico y el iodo, en los que se obtuvieron cuatro curaciones y tres insucesos. Dos casos del Dr. Richet (1880 y 1883) curados por el iodo. Varios casos del Dr. Serains (1887) curados por el iodo. Ciento y dos casos recopilados por el Dr. Jarnovsky, curados de 1876 á 1884, empleando las inyecciones hipodérmicas de ácido fénico al  $\frac{2}{100}$ . Veinte observaciones recopiladas por el Dr. Mandiola Gana, de Santiago de Chile (1890), curados todos, y en los que se empleó el ácido fénico en siete casos, el iodo en doce y el bicloruro de mercurio en uno.

Tales son los casos felices que conozco—pues prescindiendo de los no publicados, se consignan algunos insucesos—del empleo de las sustancias neutralizantes del bacillus anthracis en el tratamiento de las enfermedades carbunculosas. En todos ellos los medicamentos empleados han sido el iodo, el ácido fénico y el sublimado, con exclusión del amoníaco, cuyo poder antivirulento había sido ya indicado por Davaine; la vía de administración ha sido la hipodérmica en el sitio próximo al lugar afecto, en las partes edematosas; y las inyecciones empleadas han sido algo numerosas, habiendo llegado en el caso del Dr. Meplain á la cifra de 63, no habiendo escaseado en algunos de ellos los accidentes locales.

Este método racional, fecundo en resultados prácticos y llamado á prestar importantes servicios, no ha dejado de tener sus detractores, entre ellos el Dr. Raphael, de Provins, que comentando en la Gazette hebdomadaire de médecine et de chirurgie, Paris, 1875, algunos de los casos que antes cito, los considera á todos únicamente como curaciones espontáneas, declarando que se habrían obtenido aún sin ninguna medicación. En el año de 1880, al dar cuenta Davaine, en la sesión de la Academia de medicina de Paris del día 27 de julio, de sus experiencias y de los hechos prácticos que las habían seguido, Collin las consideró también como casos de curaciones espontáneas, á lo que Davaine contestó textualmente como sigue: “Se puede siempre hacer la misma objeción á todas las medicaciones. Cuando el sulfato de quinina cura la fiebre, se puede también decir que esa fiebre hubiera podido curarse espontáneamente. La misma respuesta podría darse á todos los que niegan la evidencia de algunos hechos, principalmente en el caso del carbúnculo, en el que un médico notable, el Dr. Joux, había dicho en 1858 que la medicina expectante en el carbúnculo equivale casi á un homicidio involuntario.” (Cavasse, Annuaire général des sciences médicales: Paris, 1859.)

Antes de concluir esta parte quiero dejar constancia de que en ninguno de los casos curados por las inyecciones neutralizantes de sustancias antivirulentas que se han publicado, se ha llevado el agente antiséptico directamente al torrente circulatorio. El método de inyecciones intravenosas en el tratamiento de las enfermedades carbunculosas es exclusivamente peruano.

Los primeros casos de él, que citaré más adelante, se refieren al año de 1882, y en el año de 1884 nuestro antiguo catedrático de patología médica, el Dr. Tomás Salazar, sin tener conocimiento de los hechos anteriores, y guiado únicamente por el convencimiento que tenía de poder atacar al bacillus anthracis en la sangre, empleó las inyecciones intravenosas de ácido fénico en un caso de pústula maligna que progresaba á pesar de la cauterización, obteniendo una curación completa.

He aquí la correspondiente historia clínica: Juan Porsales, de constitución robusta, de 29 años, se presentó á nuestra observación el 19 del pasado abril; tenía seis pústulas malignas, tres en el antebrazo derecho, una en la mano del mismo lado, otra en la sien izquierda y la sexta en el cuello. Esta última había producido una gran tumefacción de toda la región cervical. El enfermo tenía fiebre alta, disnea y un mal estar general.

Refería él que hacía tres semanas había comido carne de un novillo que había muerto en la chacra, que el 14 se le hincharon las glándulas del cuello (adenitis), que el 17 le dió una fiebre fuerte y se le hincharon también el pecho y la cara, notando entonces las seis pústulas malignas ya indicadas. El mismo 19 vimos al enfermo en consulta con el Dr. Iturrizaga, y acordamos incidir todas las pústulas y cauterizarlas con ácido nítrico, administrándole una poción tónica y antiespasmódica. El 20 se agravó el enfermo; la fiebre era más alta; la tumefacción tan considerable que producía disnea y disfagia; la inquietud del paciente era extraordinaria. Visto este estado tan grave y recordando que el exámen microscópico de la sangre en la afección carbunculosa manifiesta la existencia de un microbio (bacteria) en ese líquido, no vacilé en hacerle inyecciones intravenosas de ácido fénico; se disolvió un gramo de ácido fénico en 200 gotas de agua destilada. Se le inyectaron 50 gotas en tres venas. A las pocas horas noté una grande mejoría: se le repitió la inyección dos veces más al día. Al siguiente el alivio era mayor y se le hicieron otras dos inyecciones. Al tercer día el enfermo estaba apirético y la tumefacción había disminuido y en los días siguientes desaparecieron todos los accidentes, quedando sólo un abceso superficial en el cuello. También he sabido que otras cinco personas que comieron la carne del mencionado novillo murieron, una de ellas asistida por el Dr. C.

Esta observación es de grande importancia; prueba que los microbios de la sangre pueden destruirse con el ácido fénico llevado directamente al torrente circulatorio, el que hace que cesen todos los accidentes del virus carbunculoso.

La literatura médica no registra ningún caso de enfermedad carbunculosa tratado por el amoniaco, pues lo único que se encuentra es una vaga indicación de su uso al interior en la pústula maligna en la Tesis de Gautheret, París, 1859, y, sin embargo, las pocas observaciones que más adelante presento, incompletas como son, prueban de una manera irrecusable la potencia anticarbunculosa, si se me permite la frase, del amoniaco, y su superioridad sobre el ácido fénico y el iodo generalmente empleados. Ya antes he indicado que Davaine al hacer sus experiencias para descubrir las sustancias que neutralizan la virulencia de la sangre carbunculosa había estudiado la acción del amoniaco, y la reconoció muy poderosa en este sentido.

Sin embargo, su uso no se generalizó y siempre se ha considerado el amoniaco simplemente como sustancia excitante, pero su poder antiséptico no puede desconocerse; pruébalo su eficacia ya juzgada en las mordeduras de las serpientes y demás animales venenosos, y el ocupar el 26º lugar en la escala de Miguel (Bull. gén. de thér. méd. et chir.), á pesar de lo que no han faltado autores, como los señores Arloing, Cornevin, y Thomas, que ocupándose de la acción de los diversos antisépticos sobre el virus carbunculoso, colocan al amoniaco entre los cuerpos que no destruyen la virulencia del bacilo (Duclaux, Chimie biologique, Encyclopédie chimique de Fremy, Tome IX, Paris, 1883). Por desgracia Duclaux, al citar este trabajo, no indica el modo como se han realizado estas experiencias, que están en desacuerdo con la clínica, y con las propiedades bastante conocidas del amoniaco.

En efecto, el amoniaco, como se sabe, es uno de los cáusticos más poderosos que se conoce; aplicado directamente sobre la piel la irrita, y si su permanencia es prolongada la irritación va hasta la gangrena de los tejidos; sus vapores causan una inflamación violenta é insoportable de las membranas mucosas. Introducido al organismo por la vía estomacal produce una excitación, un aumento de la caloricidad, aceleración de la circulación, activa las secreciones urinarias y de las glándulas de la piel; pero sus efectos son bastante pasajeros porque es una de las sustancias más difusibles entre los diversos agentes terapéuticos; no bien se le ha ingerido cuando penetra al torrente circulatorio, lo recorre en toda su extensión y se elimina rápidamente del organismo. Algunos autores, entre ellos

Halford (Lo Sperimentale, 1875), creen que el amoniaco se transforma en el estómago en cloruro de amonia, sal menos antiséptica que el amoniaco en sustancia; y, teniendo esto en consideración y deseando utilizar la acción casi específica de este cuerpo en las intoxicaciones de origen animal, Halford fué uno de los primeros que lo inyectó directamente en la sangre. Es más que probable que sea esta una de las razones por la que no se ha generalizado su uso en el carbúnculo, pues es sabido que las inyecciones intravenosas en el hombre han sido siempre empleadas con mucha parsimonia. Introducido al torrente circulatorio por inyección intravenosa sus efectos son más rápidos y más marcados, siendo este uno de los medios más poderosos que posee la ciencia para levantar las fuerzas decaídas del organismo; destruye la plasticidad de la sangre, impidiendo así la obstrucción de las pequeñas radículas arteriales y venosas; y, finalmente, tiene la ventaja, administrado por esta vía, de perder su propiedad cáustica diluyéndose en la gran masa líquida de la sangre.

Su poder anti-virulento es bastante conocido: el amoniaco mata á los organismos inferiores; el aire por el que ha pasado una corriente de sus vapores se encuentra libre de todo gérmen orgánico; y, como ya lo he dicho, su eficacia en el tratamiento de los envenenamientos por las sustancias sépticas de origen animal (mordeduras de serpientes y demás animales venenosos), es cosa ya juzgada por la ciencia.

Existe una enfermedad mucho más grave que las afecciones carbunculosas, y que es originada, según los estudios de Duclaux, por el vibirion piogénico—me refiero á la septicemia (infección purulenta). Esta afección que por muchos años ha sido el oprobio de la cirugía, y contra la que han sido impotentes todas las medicaciones empleadas, se dominó por primera vez el día que un práctico tan audáz como instruido osó atacar directamente á su agente productor en el torrente circulatorio. Ninguno de vosotros puede desconocer las curaciones obtenidas por nuestro ilustrado profesor de clínica-quirúrgica, el Dr. Lino Alarco, por las inyecciones intravenosas de amoniaco empleadas en el tratamiento de la infección purulenta, muchos años antes que se conociera la naturaleza microbiótica de la afección y que se hubiera implantado la curación antiséptica de las heridas.

El amoniaco que es uno de los agentes antizímicos más poderosos que combate la postración del organismo, que puede inyectarse directamente en las venas hasta la dosis de 30 gotas; que una vez en el torrente circulatorio se difunde rápidamente, destruye á las bacterias que en él se encuentran, siendo completamente inocuo para el glóbulo, desobstruye los pequeños vasos impidiendo el éxtasis circulatorio por disminuir la plasticidad de la sangre; es el medicamento que llena todas las indicaciones en el tratamiento de las enfermedades carbunculosas.

Voy á exponer los hechos prácticos á que he hecho referencia, para después establecer las ventajas que tiene el amoniaco sobre las otras sustancias que se han empleado como neutralizantes.

*Observación I.*—En los primeros días del mes de mayo de 1882, fué conducida al Hospital de Santa Ana, y colocada en la cama No. 21, de la sala de la Virgen, servicio del Dr. Néstor Corpauchó (en el que yo era interno) la enferma Abigail Balarezo, mestiza, de 18 años de edad, soltera, temperamento sanguíneo, y constitución fuerte.

Según los datos que se obtuvieron sobre sus antecedentes, la afección que la aquejaba se había iniciado seis días antes de su ingreso al hospital, día en que estando sentada en la tapia de una de las chácaras próximas á Lima, sintió una picadura en la parte media é interna del muslo derecho. A las pocas horas se presentó un punto rojo en el sitio de la picadura, empezó á hincharse el muslo y sobrevino, al mismo tiempo, un ligero movimiento febril. Trasladada á Lima se desarrolló, según la relación del médico que la asistió, una pústula maligna muy extensa en la parte ya dicha del muslo, la que fué incindida y cauterizada con la pasta de Viena por dos veces consecutivas. Las cauterizaciones no tuvieron ningún buen resultado y el mal siguió avanzando de una manera rápida, á tal

punto que al sexto día, día de su ingreso al hospital, se encontraba en pleno período de infección, como lo demuestra el siguiente cuadro sintomático:

Decúbito dorsal, coma profunda con respiración anhelosa, la enferma no se daba cuenta de lo que pasaba á su rededor: cara roja é inyectada, ojos brillantes, lengua seca y fuliginosa, pulso á 120, pequeño, depresible; vientre meteorizado, diarreas. El muslo y todo el miembro inferior del lado derecho atacados de un edema duro é intenso; no puede darse mejor cuenta de su estado que comparándolo á una botija; los surcos invisibles que existen en la piel y que unen la base de los folículos pilosos, aparecían como anchas y profundas grietas; en la parte media é interna de dicho muslo se notaba una gran escara negra, de 20 centímetros de diámetro poco más ó menos, rodeada de un círculo rojo y brillante.

Dados los antecedentes del caso y en presencia de un estado tan alarmante, el diagnóstico no podía ser dudoso; se trataba de “una pústula maligna que había llegado rápidamente al período de infección,” y como consecuencia se desprendía un pronóstico gravísimo; esa enferma estaba irremisiblemente condenada á la muerte, con los medios de que disponía entonces la ciencia.

Se le prescribió una poción fuertemente estimulante con extracto blando de quina, cognac y 10 gramos de acetato de amoniaco, y como tópico polvos de alcanfor y cataplasmas emolientes.

Siguió con el mismo régimen por dos días durante los que no se modificó nada su estado general, aumentando el edema á tal punto que hubo que practicar dos insisiones largas y profundas á los lados de la placa gangrenosa, con el objeto de desingurgitar un poco los tejidos.

Al tercer día de su permanencia en el hospital, noveno de su enfermedad, el jefe del departamento, Dr. N. Corpancho, me ordenó le hiciera una inyección intravenosa de 10 gotas de amoniaco líquido en 10 gotas de agua destilada. La forma redondeada del brazo, la lentitud de la circulación causada por la adinamia profunda, hicieron muy laboriosa la inyección, la que pudo practicarse en una de las venas inferiores de la cara dorsal del antebrazo izquierdo. En el momento mismo de la inyección la enferma manifestó su sufrimiento por algunos gritos inarticulados, y se notó una notable reacción. En la tarde del mismo día se practicó una segunda inyección intravenosa con la misma dosis.

Al día siguiente pudo notarse una ligera remisión de los síntomas; el coma no era tan profundo; el pulso se había levantado y era menos frecuente; el edema había disminuido notablemente. Animados por este resultado se insistió en el uso del amoniaco, y continuando con la misma medicación interna se le inyectaron intravenosamente 10 gotas de amoniaco líquido en 10 gotas de agua destilada, con la orden de practicar una segunda en la tarde en caso de persistir el estado de gravedad. Esta segunda no la apliqué, por que al visitarla en la tarde noté, con gran satisfacción, una notable mejoría.

En efecto, la mejoría de los síntomas graves se acentuó más al día siguiente, á pesar de lo que, y como para confirmar la curación, se le practicó otra inyección intravenosa de amoniaco con la misma dosis.

En los días subsiguientes continuó la mejoría, persistiendo, sí, la diarrea que fué combatida con el óxido de zinc, la trementina, etc.; y, continuando con la medicación adecuada á los síntomas que sucesivamente se fueron presentando, permaneció en el hospital más de 3 meses, tiempo que necesitó para repararse la extensa solución de continuidad del muslo.

Debo hacer notar que como prueba evidente de la infección general, pudo notarse desde los primeros días de su restablecimiento una parálisis de la lengua, análoga á las que sobrevienen en los casos graves de difteria y causada, según todas las probabilidades, por alguna pequeña embolia del bulbo, sitio del origen real del nervio hipogloso, de la que se restableció lentamente.

Como accidente consecutivo á las inyecciones, aparecieron dos escaras; una en cada antebrazo, en la parte inferior de su cara dorsal, pero ni el más ligero síntoma de flebitis.

*Observación II.*—En el mismo año y en un día lunes (no recuerdo precisamente la fecha) por la mañana, ingresó al número 12 de la sala de la Virgen, servicio del Dr. N. Corpancho (siendo todavía yo su interno), una mujer india, de unos 32 años, de profesión chacarera, de temperamento linfático, constitución regular. El sábado anterior, en la tarde, había estado arreando unos carneros y se acostó sin ninguna novedad. El domingo por la mañana amaneció muy desasosegada, con los párpados del lado derecho sumamente hinchados, fiebre, pulso llano y frecuente, lengua seca y mucha sed.

Vista ese mismo día por un facultativo que tomó su afección por un flemón, le hizo aplicar doce sanguijuelas, y le administró derivados intestinales y medicamentos temperantes. El resultado de este tratamiento fué completamente negativo, y el edema siguió su marcha progresiva hasta invadir casi toda la mitad derecha de la cara.

En el momento en que la vi en el hospital presentaba el siguiente síndrome clínico: un edema duro y rojo que teniendo por centro á los párpados del lado derecho, se extendía á toda la región frontal, la región malar, invadía el carrillo del mismo lado, la mitad correspondiente de la nariz y del labio superior; pulso lleno y frecuente, piel árida, lengua seca, sed y anorexia; además se notaba en el ángulo interno del ojo dos pequeñas vesículas llenas de una serosidad sanguinolenta.

¿La etiología del presente caso y su marcha excesivamente rápida, no eran motivos suficientes para pensar en una enfermedad carbunculosa? Antes no había visto ningún caso de edema maligno, y sin embargo no vacilé en establecer ese diagnóstico, pues si alguna duda hubiera existido, había bastado para disiparla el insuceso de la medicación poderosamente antiflogística empleada la víspera.

Establecido el diagnóstico, ¿cuál era la medicación más adecuada? Los cáusticos se presentaban naturalmente los primeros; sin embargo no me atreví á hacer una cauterización extensa, tal como hubiera sido necesario practicarla, en una región tan delicada y que habría dejado como consecuencia desórdenes gravísimos. Me limité, pues, como tratamiento local, á practicar tres insisiones extensas y profundas que limitaron los párpados. La serosidad sero-sanguinolenta que fluyó de las insisiones confirmó mi diagnóstico.

Como tratamiento general pensé en el amoníaco, y tentado estuve de introducirlo por las venas, recordando el caso anterior. Pero se vacila, cuando siendo alumno se carece de la práctica suficiente, y se recuerda constantemente los inmensos peligros que los autores atribuyen á las inyecciones intravenosas. Prescribí, pues, el amoníaco por la vía estomacal á la dosis de 20 gotas en 120 gramos de julepe gomoso, para que tomara por cucharadas cada dos horas; y en el sitio de las insisiones, defensivos de agua alcoholizada con alcohol alcanforado y cataplasmas emolientes.

La remisión de los síntomas en este caso fué más marcada que en el anterior. El mismo día por la tarde pudo notarse una disminución notable del edema; disminución que se acentuó más al día siguiente, en el que se reemplazó la poción con otra que contenía extracto de quina, alcohol y 5 gramos de acetato de amoníaco.

La enferma se hubiera restablecido rápidamente á no haber sobrevenido una erisipela el jueves de la misma semana que fué fácilmente yugulada por el percloruro de hierro, y á los 10 días de su permanencia en el hospital, salió completamente curada.

*Observación III.*—Siendo interno del departamento del Dr. Morales, en el Hospital de Santa Ana, en el año de 1883, fué llevada al No. 11 de la Sala de San Antonio, una mujer, india, de 38 años poco más ó menos, chacarera, temperamento linfático, constitución fuerte. La enfermedad que la conducía al hospital era una pústula maligna en el carrillo del lado derecho; se encontraba en el octavo día de la afección, y el edema era poco extenso. Por orden del jefe del departamento, practiqué una incisión crucial y la cauterizé con el ácido nítrico; en la tarde de ese mismo día había reaparecido la zona vesicular, prueba evidente de la ineficacia del tratamiento: nueva insición y nueva cauterización con el ácido nítrico. Al siguiente día reaparición de la zona vesiculosa, aumento notable del edema que se extiende hasta el cuello, pulso lleno y frecuente, sed intensa, insomnio; se prolongan nuevamente las insisiones y se la cauteriza con el protocloruro de antimonio. En la tarde se notó una ligera remisión de los síntomas, que desapareció al día siguiente en que hubo una exacerbación marcada; aumentó el edema hasta impedir la deglución y amenazó oponerse á la respiración; había intranquilidad, fiebre, lengua muy seca, en una palabra, se iniciaban los síntomas de la infección.

Se practicó una nueva cauterización con el nitrato ácido de mercurio y un desbridamiento extenso en la región lateral del cuello, á pesar de lo que siguió su marcha progresiva la enfermedad. En este estado la enferma, vista la impotencia de los cáusticos, y recordando siempre el caso de la Abigail Balarezo, propuse al Dr. Morales practicar en dicha enferma las inyecciones intravenosas de amoníaco. El Dr. Morales accedió á mis deseos, y con su autorización hice una inyección intravenosa en la vena cefálica, con 10 gotas de amoníaco líquido en 10 gotas de agua destilada. No hubo necesidad de practicar una segunda inyección, pues en la tarde la mejoría era muy notable y esta se fué acentuando más y más en los días subsiguientes, hasta el día en que la mujer dejó el hospital con su herida todavía en vía de cicatrización, pero con su estado general satisfactorio.

*Observación IV.*—De la práctica particular del Dr. Morales, 1883: En la calle de Huancavelica; un hombre con 3 pústulas malignas en un brazo, inútilmente cauterizadas, y curadas por el amoníaco líquido empleado en inyección intravenosa.

*Observación V.*—De la práctica particular del Dr. N. Corpancho, 1883: Una mujer con una pústula maligna en la región maseterina izquierda que resistió á varias cauterizaciones enérgicas y sucesivas, y que se dominó completamente por una inyección intravenosa de amoniaco.

*Observación VI.*—La Sra. Manuela de R., de 34 años de edad, de estado casada, múltipara, mestiza, temperamento linfático, constitución regular y con cinco años de residencia en la Hacienda de Pátapo, en el Valle de Chiclayo, sintió el día 4 de junio del año de 1886, á las 3 horas p. m., la picadura de un insecto en la parte superior y externa del antebrazo derecho, picadura que fué seguida de la formación de una ligera mancha rojiza en el lugar indicado.

La noche del 4 al 5 la pasó sin novedad, pero en las primeras horas de la mañana del 5 sintió un desasosiego acompañado de dolor en la parte afecta, hinchazón y rubicundez del miembro correspondiente, notando, al mismo tiempo, un levantamiento de la mancha que había quedado en el sitio de la picadura. Para calmar el dolor y creyendo (la enferma) que se trataba de un forúnculo (chupo) incipiente, se aplicó algunas cataplasmas de harina de linaza. Pero, en vez de encontrar el alivio que buscaba, el mal siguió progresando, y en la mañana del día 6 (en que por primera vez ví á la enferma), presentaba el siguiente cuadro sintomático: 105 pulsaciones por minuto, sed intensa, poco dolor, edema de la parte superior del antebrazo é inferior del brazo derecho, rubicundez intensa, pápula negruzca en el centro y zona vesicular al rededor.

El diagnóstico no era dudoso: la etiología, la marcha rápida de la enfermedad, los síntomas locales, todo me autorizaba para diagnosticar una pústula maligna. Y, establecido ese diagnóstico, tenía que proceder tal como lo había indicado, pues se me presentaba la primera oportunidad para confirmar de un modo práctico el tratamiento que había señalado como más favorable y más en conformidad con el carácter microbiótico de la afección.

Practiqué una incisión crucial y toqué la superficie cruenta con un pincel empapado en la solución oficial de amoniaco, ordenando, para el resto del día, cataplasmas emolientes y la siguiente poción:

|                           | Gramos. |
|---------------------------|---------|
| Mucílago de goma .....    | 100     |
| Acetato de amoniaco ..... | 6       |
| Tintura de acónito .....  | 2       |

M. Por cucharadas, una cada 2 horas.

El resultado de este tratamiento fué espléndido. Al día siguiente encontré á la enferma apirética, tranquila, el edema casi había desaparecido, y la curación siguió su marcha progresiva sin accidente alguno, á tal punto que veinte días después apenas quedaba una pequeña solución de continuidad en muy buena vía de cicatrización.

Como se ve, pues, en los seis casos de afecciones carbunculosas en que se ha empleado el amoniaco, se ha obtenido la curación rápida y casi inmediata.

Estos hechos se encuentran en desacuerdo, como ya lo hemos visto antes, con las experiencias de laboratorio, de las que han deducido Arloing, Cornevin y Thomas, que el amoniaco tanto en vapores como líquido no destruye la virulencia de la bacteridia carbunculosa, pero los mismos autores han reconocido que este micro-organismo puede hacerse inofensivo sin perder su vitalidad, dato que es importante para la clínica, pues siendo el organismo inhospitalario para el microbio, le bastará una sustancia que destruyendo la virulencia del intruso, le permita utilizar todas sus fuerzas en expulsarlo al exterior.

Por otra parte, no se debe olvidar que al aplicar las experiencias de laboratorio al hombre hay que tener en consideración al organismo de este, que es el factor más importante en la producción de las enfermedades, explicándose por esto los desacuerdos bastante notables que han existido y existirán tanto en terapéutica como en microbiología, entre los químicos y los clínicos.

Veamos lo que pasa con el amoniaco y el bacillus anthracis.

La bacteridia carbunculosa una vez en la sangre se reproduce de una manera prodigiosa, su pululación activísima ocasiona la obstrucción de las pequeñas radículas arteriales, disminución en la velocidad de la corriente sanguínea, éxtasis circulatorio, lentitud en las reacciones químicas que se realizan en el organismo, y como tal descenso de la temperatura; es decir, que se realizan las condiciones favorables para su vitalidad, pues sabemos que el bacillus anthracis se desarrolla

mejor en las bajas temperaturas, y en los sitios del organismo en que la corriente sanguínea lleva menos velocidad. Si á esto se agrega que siendo la bacteridia un ser aerobio, priva á los hematias del oxígeno que necesitan para sostener la vitalidad del organismo; se comprenderá que la muerte en las enfermedades carbunculosas se realiza por asfixia y por obstrucción de las últimas ramificaciones del árbol circulatorio.

El amoniaco introducido en la sangre, disminuye su plasticidad, activa los movimientos circulatorios, eleva la temperatura; de tal modo que aún negándosele su poder antiséptico, en el caso particular del carbúnculo, siempre será provechoso su empleo, porque haciendo desaparecer las circunstancias que favorecen la pululación del bacilo, dejará á los glóbulos en mejor aptitud para vencer en la lucha que tienen que emprender con el microbio, el que vencido en ella y privado del oxígeno que necesita para su subsistencia tendrá necesariamente que aniquilarse. Pero, como ya lo he dicho antes, su poder antizímico no puede negarse, y como prueba convincente de ello, basta fijarse en la rapidez de su acción. Introducir el amoniaco al organismo, y detenerse la marcha de la afección carbunculosa, todo ha sido uno en los seis casos anteriores.

En los casos en que se ha empleado el iodo ó el ácido fénico, el restablecimiento ha sido muy lento y se han necesitado fuertes dosis de medicamento, lo que no deja de tener sus peligros; pues puede causarse una intoxicación antes que se haya destruido el agente morbífico, lo que no pasa con el amoniaco. Hay, además, otra circunstancia que debe tenerse presente en los que se refiere al iodo. Este ocupa un lugar muy elevado en la escala de Miguel: el noveno; pero, según H. de Varigni (*Les microbes et leur rôle pathogénique. Revue Scientiphique, Paris, 1885*), el iodo en virtud de su poderosa afinidad descompone las materias albuminoideas y forma con ellas productos menos antisépticos que el iodo libre; de modo que, siendo más antiséptico que el amoniaco, pierde mucho de ese poder, una vez en la profundidad del organismo. Por lo que hace al ácido fénico es más tóxico que el amoniaco y menos antiséptico que él; en la escala de Miguel le corresponde el número 43.

El amoniaco con respecto al bacillus anthracis, reúne los requisitos que deber exigirse de un agente antizímico: inocuidad para el organismo, y suficiente poder para destruir el microbio.

De todo lo anteriormente expuesto me creo autorizado para concluir que: el amoniaco es el específico de las enfermedades carbunculosas, y que debe ser el único medicamento empleado en su tratamiento, del siguiente modo:

En los casos de pústula maligna, después de la incisión depositar unas cuantas gotas de la solución oficial de amoniaco en la herida; allí destruirá las bacterias que existan, y por su propiedad eminentemente difusible llegará al torrente circulatorio antes que el bacilo, y volverá así la sangre estéril para el microbio. Esto auxiliado por el uso interno de alguna sal amoniacal, el acetato por ejemplo. A la menor sospecha de infección general, inyección intravenosa de amoniaco.

En los casos de edema maligno y de fiebre carbunculosa, debe atacarse directamente al microbio en la sangre, el amoniaco debe introducirse al torrente circulatorio. El ataque al organismo es enérgico, y la medicación debe ser lo mismo.

#### FRAMBOESIA.

By GEORGE EDMUND PIEREZ, M. D. and C. M. (Edinburgh), Antigua, West Indies.

Mr. PRESIDENT AND GENTLEMEN: The following remarks upon framboesia, or yaws, which I have the honor to lay before you to-day, are based upon some observations and a study of the disease extending over a series of years and embodied in a graduation thesis upon the subject. It was submitted to the medical faculty of

Edinburgh University in August, 1890. The disease is little known in Europe, although such renowned dermatologists as Hebra and Kaposi have described a "raspberry-like" eruption of tubercles, to which they have given the name of "framboesia;" but this disease of theirs is different altogether from that which is so frequently met with in so many of the West India islands, the west coast of Africa, and other tropical countries. It is, however, true that the real disease has been occasionally seen in England and elsewhere in patients who had brought the disease with them.<sup>1</sup> But there has not been much opportunity of studying it either in its earlier or later stages; and it is scarcely necessary to add that the chances of treatment have been nil. Framboesia is widely diffused throughout the tropics, and is very commonly met with in most of the West India islands. Take for examples the islands of Antigua, Nevis, and Dominica.

Antigua, according to the last census returns, has a population of 34,964, and the parish of St. Philip, to which I was appointed as Government medical officer in February, 1882, has a population of 3,065. From the date of my appointment to the end of May, 1889, I had treated 96 cases of yaws. The other parts of the island are also affected, and some of the cases which appear in the appendix to this paper have been brought to my surgery from neighboring parishes. Full statistics, however, are not to be got, as there is no hospital in the island for the isolation and treatment of the disease. I may add that framboesia is supposed to be extinguished in Antigua.<sup>2</sup>

Nevis has a population of 12,000. From a Royal Gazette of the Leeward Islands I copy the following notes by Dr. C. R. Edwards, medical officer in charge of the yaws hospital in that island:<sup>3</sup>

|                                              | 1887. | 1888.    | 1889.         |
|----------------------------------------------|-------|----------|---------------|
| Number of admissions into yaws hospital..... | 168   | 117      | 93            |
| Probable number of cases in the island.....  | 250   | 200      | 100           |
| Number of daily average.....                 | 22    | 24       | 24            |
| Total cost for year.....                     | £225  | £232 8s. | £219 12s. 9d. |

In the island of Dominica, population 29,000, where I had been resident medical officer of the parish of St. Andrews in 1881, and where I had seen the most aggravated forms of the disease, the local legislature had found it necessary to pass a stringent act, whereby a person afflicted with yaws could be seized by specially appointed constables and sent *nolens volens* to the yaws hospital. These measures were deemed necessary owing to the extensive prevalence of the disease among the peasantry. The following are some of the sections of the Dominica yaws act, No. 17, of 1875:

SEC. XI. Every person who shall refuse to go, to be conveyed to, or shall persistently leave or run away from the district hospital before being cured, or without the permission of the medical officer in charge thereof, or who shall bathe himself, or wash his clothing at any river or stream, except at such place or places as may be appointed for such purpose by any rule or regulation herein provided to be made, shall on conviction before a police or district magistrate, on the information or complaint of a police or other constable, be liable to imprisonment for any period not exceeding ninety days.

SEC. XIII. For harboring or concealing anyone affected with "yaws," or removing one from hospital who is under treatment, without sanction of medical officer in charge, shall be liable to any penalty not exceeding £5.

Section XVI inflicted a penalty not exceeding £5 upon anyone obstructing a constable or anybody employed under the act in the execution of his duty.

<sup>1</sup> Liveing's Handbook on the Diagnosis of Skin Diseases, p. 238, edition of 1878.

<sup>2</sup> Fox's Skin Diseases, third edition, p. 100; Med. Times and Gazette, June 26, 1880; Dr. Nicholls's Third Report of Yaws Hospitals, p. 10.

<sup>3</sup> The Gazette is dated January 30, 1890.

The compulsory segregation of yaws patients entailed a very heavy expenditure of money, which was provided for by additional taxation, according to the terms of Section XX of the yaws act. In 1876 the yaws hospitals cost the island £775, while the extra taxation brought in £1,394. In 1877 the tax amounted to £1,428, while the hospitals spent £2,058.<sup>1</sup> The attention of the home office was already engaged by the importance of the subject, and Dr. Gavin Milroy was commissioned to visit the West Indies and to report upon leprosy and yaws.<sup>2</sup>

*Definition.*—Framboesia is a specific and contagious disease, existing endemically in many tropical countries. It is characterized by an eruption on certain parts of the skin consisting of solid tubercles covered by brownish-yellow crusts, and presenting a raspberry-like appearance when the crusts have been removed. The disease runs a more or less chronic course.

*Synonyms.*—"Framboesia" (a term introduced into medical literature by Sauvages); "pian" (of the French colonies); "lepra fungifera;" "yaws" (of West Africa and British West Indies); "toboe" (a Jamaican term for a certain phase of the disease—*vide infra*); "Scwammformige" (a German name for the disease); "polypapilloma tropicum" (so called by Charlouis, and a very suitable name it is);<sup>3</sup> "buba" or "boba" (of Spanish-American and Portuguese colonies and Brazil); "patch" or "bouton d'Amboine" (of the Moluccas); "tonga" or "coko" (of the Fiji Islands);<sup>4</sup> "framosi" (of Calabar); "tetia" (of the Congo territory); "lupani" and "tono" (of Samoa); "Peruvian wart;" "parangi" (of Ceylon).<sup>5</sup>

*Geographical distribution.*—In Africa yaws is to be met with on the west coast from Senegambia in the north, as far south as Angola, together with the westerly Soudan, where it is especially frequent in Timbuctoo and Borun. It is occasionally seen in the Nile Valley, as well as on the northern and northeastern African coast line. It is very frequently met with in Madagascar, Mozambique, and the Comoros. In the East Indies it is chiefly seen in the Moluccas, Java, Sumatra, and Macassar. It is also endemic in Ceylon, New Caledonia, Fiji, and Saoma; and it is met with in the Hindu population of Pondicherry. In the West Indies it is endemic in San Domingo, Jamaica, Barbadoes,<sup>6</sup> Martinique, Guadeloupe, St. Lucia, and Dominica. It is found all over Brazil, and is said to be rather frequent at Punta Arenas, in Central America.<sup>7</sup>

*History.*—The disease, though so widely spread throughout the tropics and presenting slightly different characters in different countries, has been known to Europeans only since the introduction of negro slaves into the colonies from West Africa, its original home, whence it has spread so extensively.

In 1648 Dr. William Pison described a disease he had met with in Brazil, where it attacked not only negroes but Portuguese and Belgians as well, called "buba" or "boba," and considered to be contagious and hereditary.<sup>8</sup> In 1718 Bontius wrote about the "bouton d'Amboine," which he saw in the Moluccas. He says it resembles syphilis, but does not cause necrosis of the bones as easily as the latter disease, and is amenable to the same treatment as syphilis if taken in hand early enough. The cause, he thinks, is to be found in the climate and mode of living. In 1742 a description of yaws, as seen in the French Antilles and there known as

<sup>1</sup> From the Blue Books at the Colonial office, St. Johns, Antigua.

<sup>2</sup> Dr. Milroy's report appeared in the *Lancet*, Vol. I, p. 878, *et sequitur*.

<sup>4</sup> *Vide* Dr. Macgregor's Report upon the Coko disease of Fiji in the *Transactions of the Epidemiological Society*, Vol. IV, part I, page 55.

<sup>5</sup> Dr. Kynsey, of Ceylon, thinks parangi and yaws one and the same disease. *Vide* Dr. Radcliffe Crocker's *Diseases of the Skin*, p. 531, 1888.

<sup>6</sup> Yaws is not supposed to be found in Barbadoes. *Vide* Fox's *Skin Diseases*, third edition, p. 100.

<sup>7</sup> *Proceedings of the Royal Society of Edin.*, Vol. XVI, p. 301.

<sup>8</sup> *De Medicinâ Brasiliensi*, Lit. II, Cap. XIX, fol. 35.

"pian," was given by Dazille. This writer believes the disease to have been brought over by the negro slaves from West Africa. He considered it a variety of syphilis, modified by climate and racial peculiarities. In 1759 mention was made of yaws by Dr. Hillary, and his ideas upon the subject are the same as those of Dazille.<sup>1</sup> Dr. Winterbottom, in his account of the Native Africans of Sierra Leone, speaks of the disease, and is about the first to distinguish it from syphilis.<sup>2</sup> He says there can only be one attack of the disease, which is *sui generis* and very contagious. It can be communicated by coitus, when the genitals become the seat of the malady, whence arose the error of confounding it with syphilis. About the same time<sup>3</sup> Schilling published a work on yaws and expressed his views upon the subject. They are similar to those of Winterbottom.

In an interesting old medical treatise, published in 1749 by Dr. R. Shannon, occur the following remarks:

The yaws is perhaps one of the most remarkable diseases that prevail among negroes. It is infectious, and like smallpox, never attacks a person a second time. It is communicated by contact, most commonly the way the venereal disease is. It is seldom caught without some connection or intimate communication.<sup>4</sup>

In 1860 Dr. Victor De Rochas published his thesis on the tonga of New Caledonia and the neighboring archipelago, which, he says, though closely resembling syphilis, has nothing to do with that disease, but is a variety of yaws. Among numerous others of the older writers who considered frambœsia another word for syphilis, may be mentioned Sydenham, who thought that the peculiar characteristics of yaws were due to climatic influences; Dr. Copland, who makes the most astounding remark in his Dictionary of Practical Medicine, that the syphilis of Europe is derived from and hence identical with African yaws; the great dermatologist, Hebra,<sup>5</sup> who denies the existence of yaws as a special disease, believing it to be due to chronic ulcerations of a syphilitic, scrofulous, or lupoid origin, accidental to certain places, and proposing to call the disease "papilloma syphiliticum," or "p. scrofulosum;" and Dabny,<sup>6</sup> who mentions that he had met with a disease in China, having the characteristics of yaws, known as "yang-mey-tchoang," which he considered syphilitic in origin. Sprengel<sup>7</sup> was of the opinion that pean and yaws were two separate diseases, and Alibert<sup>8</sup> thought yaws was a sort of mycosis, divisible into the following three varieties: (1) "Mycosis framboise," characterized by small granular tumors which commonly attack negroes. (This is probably true yaws.) (2) Mycosis fungoide, characterized by fungous oval excrescences, exuding a foetid discharge. (This is probably the bouton d'Amboine of Bontius.) (3) Mycosis syphiloide, characterized by its resemblance to syphilis in its symptoms. (To this variety probably belonged the "sibbens" or "sivvens" of Scotland.) This disease (sibbens) began with ulceration of the tonsils and uvula, the ulcerations bearing yaws-like tumors. But true frambœsia never begins in this way, and very rarely, indeed, attacks the soft palate, if at all. I have never seen such a case as yet myself. Dr. Pollet,<sup>9</sup> of Lyons, thought sibbens a phase of secondary syphilis. The disease used to be met with commonly in Dumfriesshire, Galloway, and the west of Scotland, among the dissipated

and squalid, and it was acknowledged to be infectious.<sup>1</sup> Though many considered sibiens a venereal disease, others did not, and Dr. Adams thought it a malady *sui generis*.<sup>2</sup> Coming to more modern times, it is now generally admitted that framboesia is a disease by itself, and not in any way allied to syphilis or any other malady,<sup>3</sup> in spite of the belief expressed by so eminent a surgeon as Mr. Jonathan Hutchinson that "yaws is syphilis in the negro,"<sup>4</sup> a syphilis that in him gives rise to papillomatous growths.

*Symptoms.*—( $\alpha$ ) Stage of incubation: The period of incubation lasts from two to ten weeks. During this stage there are no special symptoms to be recorded, excepting perhaps slight febricula in children. ( $\beta$ ) Stage of invasion: Here, too, there is very little febrile disturbance, sometimes so slight that only a feeling of malaise is produced. Occasionally there are pains in the joints, and sometimes, but rarely, tenderness and enlargement of lymphatic glands, the latter being noticed only if the eruption is very extensive and the patient is weak and delicate. The eruption of tubercles is mature in from two to eight or nine days, and comes out in successive crops. The disease lasts, in mild cases, from two to four or six months, and in severe cases to two years or more.

*Results.*—If the disease is mild, as is usually the case in this island, no after results will follow;<sup>5</sup> but if it is severe and aggravated by poverty, want of cleanliness, and improper remedial measures (such as mercurials internally and the external application of various unsightly cataplasms<sup>6</sup>) the patients are rendered anæmic and weak, ulcerations set in, extremely difficult to heal, and death occurs from diarrhœa, or dysentery, or dropsy, or some other complication. But if recovery does take place after severe ulcerations, the patient is a cripple for life, from destruction of muscles and tendons and contractions of joints. The severer forms of the disease, though seen in some of the other islands, such as Montserrat and Dominica (where I have met with several cases myself), are not common in Antigua.

*Description and varieties of eruption.*—( $\alpha$ ) Pian dartre. Here and there, particularly on the upper and lower extremities and the face, a branny or scurfy condition of the skin makes its appearance. Sometimes the whole body may be covered over with this furfuraceous eruption in patches of various sizes. In this stage the disease is known as "pian dartre" or "yaws cacca," and it is considered by some as a distinct variety. This, however, is a mistake, for it is but a stage in the evolution of the true tubercle. The patches, consisting of loose desquamating epithelial scales, are generally round in shape, and vary in size from that of a pea to that of half a crown, or larger, their edges being slightly elevated above the surrounding skin. On close inspection these epithelial scales may be seen to be lying over numerous, very minute elevations, which are caused by the growth and gradual protrusion of the papillæ of the skin.

Plate I is a photograph of Case CXIII (*vide* Appendix). Patches of the condition known as "pian dartre" are seen on the forearms. Some fully developed tubercles also exist, below the lower lip, on forehead and neck.

( $\beta$ ) The yaws tubercle: It varies in size from that of a millet seed to that of a florin, or larger. The greater the protrusion of the papillæ of the skin the thinner becomes the epidermis, till at last, when the tubercles have fully developed, the epidermic

squames have nearly entirely disappeared,<sup>1</sup> and the surface of the excrescence presents minute, separate, but closely aggregated pink points. At this stage the tubercle is not unlike a raspberry in appearance, whence the name of the disease (from French *framboise*, a raspberry). Very soon this reddish granular surface becomes covered over with a sticky exudation, which dries up and forms a crust. It gets gradually thicker and forms the typical yaws crust. At the tubercle stage the body is covered over in certain parts by greenish-yellow, round or oval, raised scabs or crusts. They look not at all unlike lumps of crude yellow beeswax scattered about the body. Occasionally, by the growth of the crust in separate layers, a distinctly limpet-shell shape is produced; and those who are not properly acquainted with the disease may easily mistake this appearance, at the first glance, for rupia. The typical yaws crust is not seen on those parts of the body where there is moisture (vulva, anus), or where there is friction (inner aspect of thighs, axilla). Often small, brick-red, irregular spots or streaks are seen in a yaws crust, usually in the center or most elevated part. These reddish marks are due to hæmorrhages from the papillæ beneath. A narrow red edge of congested skin is seen immediately around each tubercle in patients of light complexion. A certain amount of symmetry in the distribution of yaws tubercles is very commonly met with, and branny patches are not infrequently seen scattered over the body in chronic cases, even when all traces of tubercles have disappeared. Sometimes two or more tubercles may coalesce, or one may grow to a very large size, while the others may remain small or disappear altogether. These large excrescences are known as "mama pian," or "mother yaws." Yaws tubercles give off a peculiar mawkish smell and are itchy but not very sensitive, except on firm pressure. This is a characteristic feature of the disease.

Plate II is a photograph on bromide paper of Case XC (*vide* Appendix). The tubercles in the axillæ have not the typical crust. A large number of small ones are seen around the larger ones. Those on the abdomen are of greater size and are covered over by the typical crust. The red patches of papillary hæmorrhages are seen on the crust. There are also visible two or three dark patches (or "maculæ") which indicate the site of former tubercles. *Cf.* Pl. XIII.

Plate III is a photograph of Case CVII. It shows the symmetrical arrangement of the eruption on the forearms. The dark spots in the center of each tubercle indicate that the healing process is commencing there. The healing of a tubercle means the shrinking to their normal level of the overgrown papillæ, and this process generally takes place in the center of a tubercle, though not invariably so. This photograph also exhibits four pigmented patches, or maculæ, on the leg, indicating the presence of former tubercles which have healed.

Plate IV is a photograph of Case CIII in the Appendix, and shows the symmetrical distribution of the eruption on the wrists and inner aspect of the elbows. There is also a yaws tubercle in the neighborhood of the right axilla.

Plate V is a photograph of Case C, and is another instance of the symmetrical distribution of yaws tubercles. One is particularly large on the left forearm, probably from coalescence of smaller tubercles. Two have almost "run" together on the right forearm. Hæmorrhagic patches and congested edges are also noticeable. The crusts, being freshly formed, are thin in substance.

(*γ*) *Pian gratelle*: This is a comparatively rare condition, and I have only seen one case to which this term might be applied. It is looked upon by some as a distinct variety. It consists of a collection of watery-looking, light purplish colored tubercles, without any distinct crust upon them, about the size of a No. 2

<sup>1</sup> Dr. Kynsey, of Ceylon, describes the epidermis as "splitting and curling off from the center toward the periphery." (Art. "Frambœsia" in Dr. Crocker's Skin Diseases.) This applies only to the so-called variety of "crab yaws," but is not seen elsewhere in the body where the skin is thin

shot; sometimes, as in the patient I saw, one or two true yaws tubercles may be found as well. The name "Guinea-corn yaws" has also been applied to this condition, probably from the size of the tubercles.

(δ) Crab yaws: When the disease attacks the sole of the foot it is known as "crab yaws" or "crapeaux;" but this is a name applied indiscriminately to any fissured condition of the soles of the feet, a not uncommon occurrence among the negroes, and one which is due sometimes to accidental cuts from sharp stones, etc., or to the ulcerations caused by chigres or chegoes.<sup>1</sup> In the condition of crab yaws, a group of papillæ endeavor to force their way through the thick, horny layer of the sole, with the result that the skin cracks irregularly around the growing tubercle. It is a rawer looking tubercle than that which is found elsewhere on the body, and has no crust over it. The epidermis seems as though eaten out in irregular, more or less circular layers around the excrescence.

Plate VI is a photograph of Case XCVII in the Appendix, and is a good illustration of crab yaws. The raw-looking protrusion and the irregularly eaten out character of the epidermis around it are well exhibited.

(ε) Ringworm yaws: This is another so-called variety very frequently met with. The eruption consists of more or less circular ridges, surmounted by a layer of the usual "crust," and inclosing patches of sound skin of a distinctly darker hue than that of the rest of the body. This condition is only met with in the case of the larger tubercles, and is produced by the manner in which they heal. This process consists in the gradual shrinking of the overgrown papillæ to their natural size, the shrinking sometimes beginning in the center of a tubercle and spreading toward the periphery, thus producing the ringworm-like appearance, at other times beginning at one side of a tubercle and gradually spreading across it, giving rise to yet another variety of yaws, the so-called "lupoid" of S. Kynsey.<sup>2</sup> When the yaws crusts drop off there is no cicatrix left to show the site of the tubercles but only darkly pigmented patches or maculæ, the degree or intensity of pigmentation depending upon the complexion of the person attacked. These maculæ, which may be seen scattered over the body along with other stages of the eruption,<sup>3</sup> may last for two months or more, but seldom disappear entirely even then. I have known them to last over a year.

*Duration and termination.*—It may take from two weeks to four or six months or even longer for the first crop of tubercles to disappear. Then fresh eruptions may come out and fade away in the same way, and a patient may go on thus for one or two years or longer, and eventually get quite well without any special treatment or any perceptible deterioration of health beyond, perhaps, inability to walk from the disease having attacked the feet (crab yaws). But, on the other hand, from long continuance of the disease and injudicious treatment the tubercles, instead of shrinking and disappearing, are apt to break down and ulcerate. The injudicious treatment consists in the application of poultices of crushed leaves of various kinds to the tubercles, in which, in spite of their too often seen evil results, the negroes have an undying faith. This, with neglect of cleanliness and the use of unwholesome food, impoverishes the system and renders it liable to ulceration.

Yaws ulcers are generally round and vary from the size of a 3-pence piece to that of a half-crown, or more. In Dominica I have seen yaws ulcers on the anterior aspect of the legs, their commonest position, exposing a raw surface of 3 or 4 square inches. They are punched-out looking, their edges round and hard but not swollen, and their surface slightly granular and bright red. These ulcers are said to cause necrosis of bone, but I have never seen anything so severe in Antigua.

<sup>1</sup> The chigre is the female of *pulex penetrans*, which burrows beneath the skin and lays its eggs there. Great irritation and often ulcerations are the result to the host.

<sup>2</sup> Crocker's Skin Diseases; Art. "Framboesia."

<sup>3</sup> *Vide* Plate III, where maculæ exist on the leg and fully developed tubercles on the forearms.

PLATE XI.

FRAMBŒSIA.

PLATE XII.

FRAMBÆSIA.

*Plate XIII*

Sackett & Widdowson Co. N.Y.

The following plate is a very good illustration of the ordinary form of yaws ulcers:

Plate VII, a bromide print, colored, of Case XCVIII. It will be noticed that there is symmetry in the site even of the ulcers. The black spots are maculæ.

*Distribution of eruption.*—The most common seats of the eruption are the upper and lower extremities, but chiefly the latter. Broadly speaking, those regions are least attacked that are best protected by clothing. The face, the angles of the mouth, the root of the nose, and the forehead are other favorite seats of yaws tubercles and they are frequently seen around the anus and on the genitals.

Plate VIII is a photograph of Case CXIV, showing the eruption at the angle of the mouth, as well as over the rest of the face. Some tubercles are also seen on the forearm.

The following is a photograph of Case CVIII in the Appendix. The eruption on the forehead has a somewhat serpiginous character. There are numerous small tubercles on the cheek and a large oval one on the side of the neck. The hæmorrhagic patches on the crust were well marked in this case.

Plate X is a water-color sketch of Case II. This was a mulatto lad. The tubercle on the scrotum was very large. I found no enlargement of the inguinal glands. The congested border of skin on the edge of the tubercle was well marked, as were also the hæmorrhagic points in the crust.

Although the eruption is said to occur on the hairy scalp, the interior of the mouth, and the palms of the hands, I must confess that I have never seen an example of any of them.<sup>1</sup>

The following table of 116 cases of yaws treated by me in the island of Antigua up to the end of May, 1889, will show the relative frequency of the seat of eruption of yaws tubercles:

|                         | Cases. |                             | Cases. |
|-------------------------|--------|-----------------------------|--------|
| Face .....              | 15     | Genitals and perineum ..... | 7      |
| Upper extremities ..... | 32     | Universally diffused .....  | 9      |
| Lower extremities ..... | 48     |                             |        |
| Trunk .....             | 5      | Total .....                 | 116    |

For the sake of comparison I append the following table from Dr. Nicholls's Third Report of Yaws Hospitals to illustrate the chief seats of distribution of yaws eruptions:

|                     | Cases. |                       | Cases. |
|---------------------|--------|-----------------------|--------|
| Face and head ..... | 49     | Upper extremity ..... | 29     |
| Trunk .....         | 20     | Lower extremity ..... | 70     |
| Genitals .....      | 16     |                       |        |
| Perineum .....      | 20     | Total .....           | 204    |

Dr. Nicholls has seen tubercles on the scalp in only three out of the above cases, but not once in the axilla. In my own experience I have never seen the eruption on the scalp, but have often met with tubercles in the axillary region. See Plates II and IV.

The following plates are front and back views of Case CIV. They are good illustrations of a diffuse distribution of the yaws eruption. It is to be noticed in this photograph again that there is a symmetrical arrangement of the eruption.

Plate XIII is a life-size photograph of the yaws tubercles on the trunk of the young man, Charles Spencer, Case XC in the Appendix. (For another photograph of the same, see Pl. II.) The irregular and pitted condition of the surface of the crusts is indicative of its age, for when freshly formed it is smooth. (*Vide* Pl. v.) Numerous small excrescences are seen around the larger ones. These large tubercles are sometimes called "mother yaws."

<sup>1</sup>The only exception of a palmar site of a yaws tubercle I have seen was in the case of Frances Bowers, *vide* Appendix, case No. 134.

*Age and sex.*—Both sexes are equally attacked by the disease. Of 116 cases seen by me 57 were males and 59 females, and of 100 cases referred to by Dr. Nicholls<sup>1</sup> 58 were males and 42 females. Age, however, has a predisposing influence in the production of yaws, for the young are more easily affected than adults. The following table shows the ages and the relative frequency of attacks in 116 cases:

|                               | Cases. |                     | Cases. |
|-------------------------------|--------|---------------------|--------|
| 1 year and under .....        | 7      | Over 20 years ..... | 13     |
| Between 1 and 5 years .....   | 49     |                     |        |
| Between 5 and 10 years .....  | 31     | Total .....         | 116    |
| Between 10 and 20 years ..... | 16     |                     |        |

The following analysis of 466 cases is given by Dr. Nicholls:<sup>2</sup>

|                             | Cases. |                             | Cases. |
|-----------------------------|--------|-----------------------------|--------|
| Under 5 years .....         | 82     | 20 years and under 30 ..... | 49     |
| 5 years and under 10 .....  | 142    | 30 years and upward .....   | 74     |
| 10 years and under 15 ..... | 82     |                             |        |
| 15 years and under 20 ..... | 37     | Total .....                 | 466    |

*Diagnosis.*—( $\alpha$ ) psoriasis and the condition known as “pian dartre:” In the latter there is no inflammatory thickening of the skin, with redness, such as exists in psoriasis. Again, the seat of psoriasis patches is typical of that disease, viz., the elbow and knee below the patella; there is no such predilection for any particular spot of the body in the case of pian dartre. Psoriasis patches are itchy and irritable; pian dartre is not. Lastly, there often exists with pian dartre other forms or stages of the yaws eruption (such as tubercles) to indicate the true nature of the disease.

( $\beta$ ) Eczema squamosum and pian dartre: In the former disease there are often other varieties coëxisting with the squamous condition, such as the weeping form, which will be sufficient to distinguish the two maladies.

( $\gamma$ ) Yaws and syphilis: So much doubt has prevailed, even up to recent times,<sup>3</sup> with regard to these two diseases, that a few words must be devoted to the differential diagnosis between them. It is now generally held that the two are entirely distinct; but there were many, whose names are too familiar in medical literature, who have been of opinion that yaws was really syphilis modified by climate and racial peculiarities (Dazille, Sydenham, Copland, Kaposi, and, coming to recent times, Jonathan Hutchinson). Some of the chief points of difference between the two diseases are the following: (1) Syphilis has a predilection chiefly for mucous surfaces; yaws chiefly affects the skin. (2) The lymphatic glands are always enlarged in syphilis; in yaws this is seldom seen, except in severe cases with debilitated constitutions. If the eruption was of syphilitic origin in Case II, vide Pl. x, the inguinal glands would most assuredly have been enlarged; but I have made the remark that these glands were not enlarged. (3) Syphilitic eruptions are not itchy; yaws tubercles are. (4) A coppery color is characteristic of syphilitic eruptions; the crust is distinctive of yaws tubercles. (5) A chancre or indurated sore always occurs at the spot of inoculation with syphilitic virus; whereas in yaws the eruption breaks out not necessarily at the site of inoculation, but elsewhere on the body. (6) Syphilis causes necrosis of bones; yaws never does, except as a result of chronic ulcerations. (7) A patient suffering from secondaries can not contract an indurated sore; but a patient with yaws poison already in his system can have on a healthy part of his skin fresh tubercles by inoculation of that part with yaws virus. This was found out in 1867 by Dr. Gama Lobo, of Brazil.<sup>4</sup> (8) Yaws is more common in young children, but not as a congenital disease. Very commonly the parents are perfectly healthy and clean

<sup>1</sup> Third Report of Yaws Hospitals.

<sup>2</sup> *Op. cit.*

<sup>3</sup> *Vide* Brit. Med. Journal, April 16, 1892, p. 815.

<sup>4</sup> Dictionnaire Encyclopédique des Sciences Médicales, Art. “Framboesia.”

skinned, while the child may have yaws tubercles. Again, only one child might be affected in a family of three or four. If yaws was syphilis more than one at least would be diseased. (9) Lastly, and this is most positive proof of the non-identity of the two diseases, if such were really needed, syphilis and yaws have coëxisted together, each running its own course and displaying its own characteristics. Such a case was seen by Dr. Gavin Milroy in the public hospital of Kingston, Jamaica.<sup>1</sup> Charlouis,<sup>2</sup> surgeon to the Dutch army in Java, inoculated a patient suffering from frambœsia with syphilitic virus. The result was that a typical case of syphilis was produced, which did not affect the course of the frambœsia.

*Prognosis.*—In otherwise healthy children or adults the disease is not grave, and needs no special treatment beyond cleanliness and wholesome food. Successive crops of the eruption may come out from time to time, and the skin may get quite free from tubercles in from one to six months. So little is thought of the disease by the negroes themselves, who are the chief sufferers, and who generally use their own tisanes and cataplasms in the treatment of the disorder, that healthy children have been known to have been specially inoculated with yaws by their mothers as a prophylactic measure against other and more serious maladies. This fact came within the personal knowledge of the late Dr. B. Johnson, of Montserrat, as having really taken place there; and the late Sir John Gorrie informed me that it was a common practice with the natives of the Fiji Islands. In the older days of slavery mothers used to give their children yaws, not to protect them against other diseases, but as an excuse from doing work on the estates, the afflicted children needing all maternal care and attendance at home.<sup>3</sup> The prognosis is not, however, so favorable in those who are already of delicate constitution or the subjects of the scrofulous diathesis. For here the patients become thin and anæmic, and the "tubercles," instead of gradually shrinking and fading away as is generally the case, are apt to break down and ulcerate. Deeper structures, as muscle, tendon, and bone, may then be involved, giving rise to deformities of various kinds, or death may result from some intercurrent affection, as diarrhœa or dysentery or dropsy.

*Etiology.*—( ) Predisposing causes: (1) Race. It is generally believed that yaws attacks only the negro, or black race. This, however, is an erroneous impression, although most of the cases met with occur among the negroes; for to whomsoever the virus is applied, especially if the cuticle is broken, be he black or white, the disease will manifest itself in due course. It is chiefly the poorer class of negroes who are affected, those who are generally dirty in their habits, poorly clad, and badly fed and housed. They are thus more exposed to the contagion. The mulatto population of these islands are, as a rule, better off, and are more cleanly and intelligent; thus the chances of contagion in their case are greatly reduced, while in the case of the whites the risk of contracting the disease is reduced to a minimum. The following is an analysis of 116 cases, and exemplifies the relative frequency of the disease in different races:

|                           | Cases. |
|---------------------------|--------|
| Black (negroes) .....     | 105    |
| Colored (mulattoes) ..... | 9      |
| White (Portuguese) .....  | 2      |

That the disease was not peculiar to negroes alone was noticed by Dr. Shannon,<sup>4</sup>

<sup>1</sup> *Vide* Med. Times and Gazette, Vol. II, p. 515.

<sup>2</sup> *Edin. Med. and Surg. Journal*, November, 1882, p. 468.

<sup>3</sup> A mention of this dodge having been practiced in St. Kitts is to be found in an old book, published in 1801 (p. 158), called "Letters on the Cultivation of the Otaheite Cane, the Manufacture of Sugar and Rum, the Saving of Molasses, the Care and Preservation of Stock, with the Attention and Anxiety which is due to Negroes," by Clement Caines, Esq.

<sup>4</sup> *Practical Observations on the Operation and Effects of Certain Medicines in the Prevention and Cure of Diseases to which Europeans are Subject in Hot Climates*, p. 380.

who says: "Several of the soldiers were affected by it," and further on<sup>1</sup> "yaws is frequently contracted by the European sailors in the slave trade." A former governor of this colony, the late Sir ———, informed me himself that he had had an attack of yaws while serving on the west coast of Africa. I may remark that in my two white patients the eruptions presented the very same appearances as those already described as occurring in the negro. Mr. Jonathan Hutchinson's syphilitic origin of yaws, with tendency to papillomatous growths, in the negro will hardly hold in white races. The theory needs remodeling on very different lines.

(2) Food: Some of the older writers believed that yaws arose from the use of bad food (such as semiputrid meat or fish), and from insanitary surroundings and dirt. But these conditions act as predisposing causes only by lowering the vitality of the individual.

(β) True cause: Yaws is a contagious disease, depending for its spread upon the presence of a specific virus, a microbe. It is not hereditary or infectious. Inoculation may take place by application of the poison to such thin skin as exists on the lips or genitals; hence, it is often spread by sexual intercourse and by diseased mothers to their children, at the breast.<sup>2</sup> It may also be produced in a position where the skin is thicker. For instance, Dr. Bowerbank, of Jamaica, painted the inner aspect of the arms of three young girls for a few minutes during two days with a feather wet with yaws virus, and the disease appeared on them on the twentieth day.<sup>3</sup> But the disease occurs all the more readily and surely if there is any abrasion of the cuticle, and flies<sup>4</sup> may thus become the medium of infection and cause the spread of the disease, though there may be no actual contact of the healthy with the diseased. Dr. Gavin Milroy, in his Report on Leprosy and Yaws, submitted to the secretary of state for the colonies, made a statement to the effect that he thought yaws under certain conditions contagious, by contact of the healthy with the diseased, but that he did not believe contagion to be the sole cause of the spread of the disease amongst a community. He mentions the fact, given by Dr. Crane, of Trinidad, that patients suffering from yaws were admitted into the general hospital of that island and that nevertheless there was no spread of the disease amongst the inmates of the institution. On the other hand, however, Dr. Espinet, also of Trinidad, says that a case of yaws was admitted into the leper asylum of that island and that several cases had arisen after it.<sup>5</sup> But does the mere fact of there being no spread of yaws in the Trinidad general hospital, after admission therein of an infected case, either prove or disprove the theory of contagion? Surely not. Unless there be inoculation of the system, either directly by contact or indirectly by flies, or other means, with the "*materies morbi*," no result will follow, and I hold that Dr. Gavin Milroy's statements are founded upon insufficient observations. As proof of contagion from nursing mother to child, I give the following cases from the Appendix:

*Case XLIX.*—Margaret Henry, æt. 35 years, negro, from the village of Willikies, in this island, came to my surgery on June 13, 1885, with yaws eruptions on forearms, legs, face, and breasts. She had noticed them since the end of the previous month.

*Case XLVIII.*—Louisa Thomas, æt. 1 year, illegitimate child of the above, was brought to me on the same day (June 13) by its mother, who said the child showed the disease on June 8. It had been perfectly healthy before. On examination I found yaws tubercles at the angles of the mouth and on the cheeks.

<sup>1</sup> *Op. cit.*, p. 557.

<sup>2</sup> Edin. Med. and Surg. Journal, April, 1827. Also compare my cases 48 and 49, *infra*.

<sup>3</sup> Dictionnaire Encyclopédique des Sciences Médicales, Vol. iv., art.: Frambœsia.

<sup>4</sup> *Vide* Crocker's Skin Diseases.

<sup>5</sup> Dr. Nicholls's paper in Med. Times and Gazette, January 3, 1880.

The following cases from the Appendix are given as exhibiting proofs of contagion by direct contact:

*Case LIV.*—Mrs. Gilead, æt. about 35 years, negro laborer, from the village of Newfield, Antigua, came to see me on September 24, 1885. She had yaws tubercles on forehead, arms, and legs, with some maculæ as well. She had noticed the eruption about a week previously. She could not say where she had contracted the disease, but one of her children had had it up to the end of July, 1885.<sup>1</sup>

*Case LVII.*—Edward Gilead, æt. 50 years, negro laborer, husband of Case LIV, from Newfield village, came to my surgery on October 12, 1885, with yaws tubercles on forehead, angles of the mouth, arms, and legs. He had noticed them on the 5th of October, and is sure he had contracted the disease from his wife.

*Case LV.*—Edgar George, 10 months, illegitimate son of Mary Adams, negro laborer, from Willikies village, was brought to me on October 4, 1885, suffering from yaws of two days' duration. Mother could not say where her child had got the disease, though the disease was prevalent in the village at the time. By the third week of December the child was perfectly well, only a few maculæ being seen.

*Case LXVIII.*—Mary Adams, mother of the above, came to me on January 3, 1886, with well-marked yaws eruptions on arms, legs, and buttocks. She said she had had them for about two weeks previously (that is, about the 20th of December). The child had always slept with her and she had been nursing him, and she is sure she had caught the disorder from him, as she had not seen or come in contact with anybody else suffering from the disease.

*Case LXXII.*—Archibald Philo, æt. 5 years, negro, from Betty's Hope estate, was brought to my surgery on August 10, 1886, with yaws eruptions on face, arms, legs, and buttocks. He was all right by the end of the month.

*Case LXXIII.*—Beatrice Philo, æt. 6 years, sister of the above, was brought to me on September 6, 1886, with yaws tubercles on face, arms, legs, and genitals. She was quite well by end of October. She had always slept with her brother, and the mother did not think there were any other cases of the disease on the estate.

*Case LVIII.*—Eleanor Thomas, æt. 3 years, illegitimate child of Sarah Bartley, from Freetown village, was brought to me on October 18, 1885, with yaws eruption on arms, legs, genitals, and anus. She had had the disease since the middle of September, 1885. The mother could give no history of contagion. She was well by the 7th of December, 1885.

*Case LIX.*—Susanna Thomas, æt. 4 years, sister of the above, came to see me on the same day with an almost identical distribution of the eruption. The mother had noticed Susanna's spots on the arms and legs at the end of September, and said that the two children always slept together.

*Case CVI.*—Catherine Richards, æt. 16 years, negro, from Liberta Village, came to me on January 17, 1889, with the disease well marked on face, arms, and legs. She had had it four months previously.

*Case CXIII.*—Henrietta Richards, æt. 12 years, a sister of the above, came to consult me on February 9, 1889. She had had yaws two weeks previously and had always slept with Catherine, to which fact she attributed her own illness, as she had not come across anybody else in the village with the disease.

*Case CIX.*—Lucy Rodish, æt. 10 years, a Portuguese girl of unmixed blood, from the village of Sweets, was brought to me on February 6, 1889. She had a typical yaws eruption on arms, shoulders, and legs. Her mother had noticed it a few days before.

*Case CXV.*—Caroline Rodish, æt. 15 years, sister of the above, came to my surgery on May 15, 1889. The mother had noticed the eruption first upon the arms about the middle of April. At the time of her visit to me the eruption was a general one all over the body. The two sisters were always together, and were in the habit of occupying the same bed. I may mention that the eruption in these two white cases (as well as in another, Case CXVIII in the Appendix) presented identically the same characteristics as those observed in negroes.

*Case CXVI.*—Eliza Bailey, a colored girl (mulatto), æt. 8 years, also from the village of Sweets, was brought to me on May 15, 1889, by her mother, who is a Government midwife and an intelligent woman. She says Eliza first had the tubercles toward the end of February, 1889, that she was a great friend of Lucy Rodish (Case CIX *supra*), and that she was sure her daughter had contracted the disease from her playmate.

<sup>1</sup> Vide Case XLVI, in the Appendix.

*Immunity from second attacks.*—A great many writers have expressed the opinion that there can only be one attack of the disease. Among these may be mentioned Winterbottom,<sup>1</sup> Schilling;<sup>2</sup> and Shannon,<sup>3</sup> who says "it is infectious, and like smallpox never attacks a person a second time"; Liveing,<sup>4</sup> who writes, "One attack is believed to afford decided protection against a second inoculation, but the affection is very liable to relapse;" Dr. Paulet, who inoculated five times negroes who had been thoroughly cured of the disease but failed to produce a second attack in them;<sup>5</sup> the late Dr. Imray, of Dominica; Dr. Rankine,<sup>6</sup> and many others. Others again hold that a second attack may occur after a patient has had yaws and has gotten quite well from it (Drs. Bowerbank, of Jamaica, and Nicholls, of Dominica).<sup>7</sup> For myself, I must own that I am somewhat in doubt as to the absolute correctness of these second attacks; I am more inclined to look upon them as relapses. The following are examples from my list of relapses:

*Case IX.*—Bobby Thwaites, æt. 6 years, from the village of Willikies, was first brought to me for treatment on November 10, 1882. He was quite well by end of December. On April 30, 1883, fresh tubercles were noticed on his body. He was well again by the middle of May.

*Case LXVI.*—Samuel Lawrence, æt. 4 years, from the village of Seatons, was first treated by me for well-marked yaws of three weeks' duration on December 16, 1885. By the end of March, 1886, he was quite well. In the middle of August, about four and one-half months after his recovery, he was brought back to me with a fresh attack of the disease.

Cases XXXI and CXXVIII in the Appendix are other cases of relapse. Dr. Nicholls<sup>8</sup> gives short summaries of the histories of a few of his cases of reinoculations. In one of these (case 480) the patient was perfectly well for ten and one-half months, and then he contracted the disease again; in another (case 356) eleven months of health intervened between the first and second attacks. While at the Prince Rupert's Hospital he noticed second attacks coming on a year or two years after the first attacks were got rid of.<sup>9</sup> Although I look upon my own cases as examples of relapses, still the instances given by Dr. Nicholls have the appearance rather of fresh inoculations. I have found it impossible in my own cases to trace the source of reinfection, except it lay in the yaws crust. The crust contains the inoculable virus, and is easily rubbed off or may fall off when dry, often without the patient's knowledge. These fresh attacks, then, may arise from the crusts adhering to the clothes or lying on the dusty, dirty, and too-often unboarded and uncovered floors of the huts, where the naked negro child is always to be seen sprawling.

*Pathology.*—Whether there are lesions to be found in the internal organs, such as the liver or spleen, in cases of yaws I am not able to state from personal knowledge, never having had the opportunity of holding post-mortem examinations in such cases. But Van Leent, of Batavia,<sup>10</sup> states that the lymphatics are dilated and the glands engorged, sometimes containing purulent fluid. He has seen caseous deposits in the lungs, kidneys, liver, and spleen, and also in the muscles.

cartilages, ligaments, and bones. With regard to the minute structure of a yaws tubercle, it may be stated that it consists essentially of a dermatitis affecting the horny and mucous layers and the papillary stratum. The following is a vertical section of a tubercle as seen under a low power (Leitz, Ocular 2, Obj. 3); it was stained with alum carmine.

Plate XIV. The papillæ are enlarged and elongated. Large numbers of leucocytes are finding their way through the epidermis to the surface of the skin. There is also seen an abundant proliferation of cells and a good deal of organized tissue spreading upward through the horny layer. This organized tissue consists of delicate fibrils issuing from the rete Malpighii, crossing and intercrossing each other, and often inclosing patches of epithelial squamæ. This organized new tissue is highly vascular, and may be seen in two or three places to pierce the epidermis and to lie over and cover it. (*Vide a* in plate.) Several blood vessels seen cut across (*b* in plate). Under a high power numerous micrococci are seen scattered throughout the substance of the tubercle, but chiefly in the upper layers of the dermis. Along the surface of the epidermis and stretching below it are seen large numbers of micrococci, many being contained within leucocytes. These coccus forms are especially abundant in the large cells found at the junction of the horny layer with the rete Malpighii, or the layer of Laugerhaus. Many of these cells are quite full of micrococci. (*Vide plate.*)

Plate XV is a vertical section of a yaws tubercle, stained with methyl blue, and decolorized with solution of iodine and iodide of potassium. (Leitz, Oc. 3, Obj. 7.) ( $\alpha$ ) leucocytes, ( $\beta$ ) micrococci.

*Bacteriology.*—A bit of yaws crust was teased out in distilled water, treated as a cover-glass specimen, and stained in methyl blue. (See Pl. XVI.) Leitz, Oc. 3, Obj. 7, numerous bacilli seen singly and in twos or threes, the single rods measuring about  $2\ \mu$  in length and about  $0.5\ \mu$  in breadth. Large numbers of leucocytes also visible, and micrococci and bacteria. On inoculating a tube of sterile beef broth with the solution of yaws crust in distilled water a cloudiness was produced in two days, and a film was seen on the surface. They both gradually became of an amber color. Under the microscope crowds of vigorously motile bacilli were visible singly, in short chains, and in long leptothrix threads. The single rods were of the same size as those already referred to in the fresh specimen. A sterile tube of nutrient jelly was next inoculated from the broth. In two days a cloudiness appeared in the track of the needle. Microscopically the same appearances were observed as in the case of the broth. (*Vide plate.*)

Plate XVII is an artificial culture of yaws crust in sterile nutrient jelly, magenta staining. (Leitz, Oc. 3, Obj. 7.)

I may mention that the jelly was rendered slightly diffuent at the end of three weeks' growth. On examining the jelly microscopically, four days after plate 17 was painted, I found very few bacilli, but in their stead countless myriads of shining oval spores, measuring about  $1\ \mu$  in length and  $0.5\ \mu$  in breadth. The few bacilli visible were seen to contain oval, shining spores. These bacilli were never seen by me in the substance of the tumor; they were absent from yaws crusts that were protected by clothing. They are only found in old and exposed crusts. I have therefore come to the conclusion that they are contaminations, and are of the nature of the ordinary bacillus subtilis. A drop of blood was taken from the finger of a patient suffering from yaws (not close to any eruption), the surface of the finger having been previously sterilized. The specimen was dried on a cover glass and stained with magenta. Numerous coccus forms were seen scattered about the field (*vide* Pl. XVIII) amongst the red blood corpuscles, some of them adhering to the cells. These micrococci vary in size from  $0.3\ \mu$  or  $0.4\ \mu$  to nearly  $1\ \mu$  in diameter.

Plate XVIII is a cover-glass specimen of blood of yaws patient, magenta staining. (a) White corpuscle; (b) red cells; (c) micrococci. (Leitz, Oc. 3; Obj. 7.)

With the usual antiseptic precautions a tube of sterile beef broth was inoculated with the blood of the same patient. In three days the broth was found turbid; there was no pellicle formed on the surface. This proved that the growth belonged to Pasteur's anaërobic group of microorganisms. Under the microscope a luxuriant crop of micrococci was seen, singly, in twos (diplococci), and in small clusters. They were of the same size as those described in Plate XVIII. From this tube a second of sterile, solidified hydrocele fluid was inoculated. In three days a cloudiness appeared in the track of the stab, and the jelly was rendered slightly diffuent on the surface. A week after the jelly was more fluid on the top. The grayish-looking opacity that the microorganisms first presented gradually gave way to a salmon color. Microscopically, the growth presented the same appearances as that already described in the broth tube. A scraping from a patch of pian dartre was next stained and examined. In it were found a large number of coccus forms, of the same size as those already described, singly, in twos, and in small clusters, many of them being seen adherent to the epithelial scales of which the scraping consisted. There were also a few bacilli, which on artificial culture were found to be identical with those already described (and figured in Plate XVII).

*Inoculation experiments.*—With the artificial culture of the bacilli in the crust I made several inoculations on animals (fowl, dog, cat), but without any result whatever. I also tried it on my own person, without any effect. With the artificial culture of the micrococci from the blood of my yaws patient, I repeated the inoculation experiments I had previously tried with the bacilli. There were no results in the case of the fowl or dog, but there was success with the cat. I used the inner aspect of the left ear for inoculation. After the expiration of three weeks I noticed a small swelling on the upper or outer aspect of the right ear, which daily enlarged and in a few days presented the unmistakable appearance of a yaws tubercle. There was also one on the face, over the nose, but none of them showed any crusts, probably from the hairy nature of the site.<sup>1</sup> I also inoculated myself with the micrococcus culture, but beyond the fact that the site of inoculation was itchy, red, and slightly swollen for about a fortnight after the operation, there was no result. From the above-detailed experiments, I have come to the conclusion that the bacilli found in the crusts are contaminations from without, and allied to bacillus subtilis, and that the true cause of the disease yaws is a micrococcus, which I took the liberty of christening the micrococcus frambœsiæ in my "graduation thesis," submitted to the medical faculty of Edinburgh University in August, 1890.

*Treatment.*—In mild cases of the disease very little need be done. Indeed, the physician is seldom consulted except when all home remedies have failed, and the patients begin to show signs of debility from long duration of the malady, or when ulcerations break out too stubborn to be managed by the natives themselves. If the patient gets a good diet, and if, particularly, he is kept clean, the disease will run a course of from two to four months and entirely disappear. Dr. Shannon<sup>2</sup> says:

If a negro that has contracted the disorder be put in circumstances favorable to general health; if he be not obliged to work; if he be allowed a good diet; and if he be kept clean by constant washing it will run its course and after a time disappear entirely. \* \* \* The African negroes cure yaws and the venereal disease

<sup>1</sup>I may mention that these tubercles lasted for two weeks, and when they disappeared two bald patches were left behind.

<sup>2</sup>Pract. Observations on the Operations and Effects of Certain Medicines in the Prevention and Cure of Diseases to which Europeans are Subject in Hot Climates, by R. Shannon, M. D., p. 380.

by sea bathing and promoting the perspiration by drinking plentifully of a decoction of camwood<sup>1</sup> sharpened with sour palm wine, and at other times with lime or lemon juice.

In some of the West India Islands, such as Dominica<sup>2</sup> and Jamaica<sup>3</sup> the negroes are in the habit of using mercurials internally, up to the point of salivation, with sarsaparilla. This had the effect of producing anæmia and debility. But in Antigua this treatment is not in vogue, the only remedies in use being the external application to the eruption of blue stone, or verdigris, or indigo, or lime juice, or the irritating sap of the "dagger,"<sup>4</sup> combined with the internal use of tisane, or decoctions of sour-sop<sup>5</sup> leaves, or vervain,<sup>6</sup> or other equally harmless plants. Before the abolition of slavery mild cases of yaws were always treated by some of the old women upon the sugar estates, who were supposed to know the secret of curing the disease. These sages were known as "yaws grandies." But there was also great care taken of the slaves by the proprietors in some of the islands, as Jamaica,<sup>7</sup> for instance; for many estates had yaws hospitals, where patients were isolated and properly treated and cared for. The following is the treatment I have pursued in my practice:

( $\alpha$ ) *Mild cases*.—Here I only use the external application of a mild germicide ointment, as the red oxide of mercury (5 grs. to  $\zeta$ i of adeps). The patient should be well washed with plenty of soap and water, the crusts removed when softened, and the ointment should be well rubbed over every tubercle. The patients, generally children, should not be allowed to dabble in dust and dirt, and not be permitted to play with healthy children. This simple treatment I have found most successful in all mild cases.

( $\beta$ ) *More severe cases*.—Here, besides the external application of the same ointment recommended in class  $\alpha$ , I have been in the habit of giving arsenic and iron, gradually increasing the doses of the former, with great benefit.

( $\gamma$ ) *Severe cases*.—These patients are always emaciated and anæmic, and have to be put upon a tonic treatment at once. I generally combine sulphate of quinine with the iron and arsenic mixture, and I do not hesitate to increase the arsenic. I also increase the strength of the ointment I have recommended by using 10 or 15 grains of the red oxide of mercury to  $\zeta$ i of adeps. I sometimes use Tr. iodi. (P. B.) in this class as an external remedy when I find the ointment inefficacious.

( $\delta$ ) *Ulcerations*.—These are very stubborn to manage, and if tonics are indicated in class  $\gamma$  they are more so here. If tubercles coexist with ulcers they should be treated as suggested in class  $\gamma$ . The ulcers are treated by the application to them once every second day of a solution of chloride of zinc (20 grains to  $\zeta$ i aqua), an ointment of zinc oxide or iodoform being applied on lint in the intervals. If this treatment fails the ulcers should be painted once a day with the strong tincture of iodine (Edin. Ph.) or the liniment of iodine, and then tightly strapped with strips of emplastrum resinæ in such a manner that the edges of the ulcers may be approximated.

( $\epsilon$ ) *Crab yaws*.—This condition I have known to last longer than any other form of the disease, simply because of the unfortunate position of the tubercles, rest and cleanliness being almost impossible of attainment in the particular class of patients under consideration, except in hospital practice. A strong solution of zinc chloride (30 grains to the ounce) should be applied with a brush to the tubercles three times a week, an ointment of zinc oxide, or iodoform, or resorcin

<sup>1</sup> A leguminous plant, *Cassia nitida*, which produces a red dye.

being applied in the intervals. I can confidently recommend this form of treatment, but it must be remembered that no form of treatment will be of any avail in these cases unless there are absolute rest and cleanliness of the parts. The peculiar eaten-out-looking patches on the soles of the feet remain long after every other trace of the disease has disappeared, and serve as a proof of an antecedent attack of yaws. In many of my adult cases rheumatic pains in the joints were complained of after the disappearance of yaws. Here iodide of potassium has done good. Besides arsenic and iron as general blood tonics and a good diet, cod-liver oil is of benefit, especially in weakly children. In several of my cases I have tried chaulmoogra oil, both externally and internally, as well as gurjon oil externally, but I have not found them of any use. With regard to the internal administration of mercurials, I can not say that I can approve of it, although recommended by several writers. I have never seen any necessity for its use, all my patients having been easily enough cured by the treatment that I have recommended.

*Classification.*—In Fox's Diseases of the Skin,<sup>1</sup> yaws is placed under the head of the exanthemata, but somewhat doubtfully; and in the Medical Times and Gazette,<sup>2</sup> Dr. Gavin Milroy says that the disease belongs to Cullen's class of cachexiæ, or "those diseases which consist in a depraved state of the whole or of a considerable part of the habit of the body, without any primary pyrexia or neurosis combined with that state." In the Nomenclature of Diseases, by the Royal College of Physicians, yaws is placed in class D of the following table:<sup>3</sup>

*General diseases.*

|                                        |                                                                                                                |
|----------------------------------------|----------------------------------------------------------------------------------------------------------------|
|                                        | (A) Diseases dependent on morbid poisons (specific febrile disorders).                                         |
| Diseases dependent on external agents. | (B) Diseases dependent on external agents other than morbid poisons (as animal and vegetable parasites, etc.). |
|                                        | (C) Developmental diseases.                                                                                    |
|                                        | (D) Not classified (yaws-parangi.)                                                                             |

Dr. Liveing<sup>4</sup> thinks it is a general constitutional disease, and classes it with dermato-syphilis and elephantiasis Græcorum; and one of the recent treatises<sup>5</sup> on skin diseases has yaws classified under neoplasmata, or new growths—a wise classification, in that it avoids all theories and doubts. With regard to the propriety of placing framboesia under the head of "cachexiæ," I have no doubt in my mind that there are no just reasons for doing so. A cachectic condition is not characteristic of yaws, and is only seen exceptionally in those patients who have been ailing very long, or who are the subjects of ulceration. When once framboesia has been perfectly cured there occurs no sequelæ, and the system is again thoroughly restored to health. Besides, there is no suspicion of a hereditary tendency to the disease. I therefore do not look upon it as a constitutional disease to be classed with syphilis or leprosy. It is a disease caused by the entrance into the system of a specific microorganism (the micrococcus framboesia), which has a predilection for the cutaneous system, producing by its presence there an irritation and a growth of the deeper layers. Although pyrexia is a marked feature of all the exanthemata and although framboesia is ushered in without febrile symptoms of any consequence, still there is no doubt that there is some rise of temperature in most cases, even though that be slight. It must not be forgotten that these cases occur, not in hospital practice where patients can be carefully watched, but among an ignorant and untrained class of negro laborers.

Taking all the symptoms of yaws into consideration I have been led to the conclusion, aided by a not inconsiderable experience of the disease in Dominica,

Montserrat, and Antigua, that frambœsia belongs properly to the class of exanthemata, and should be placed under heading A of the table quoted from the Nomenclature of Diseases.<sup>1</sup>

## FRAMBOESIA IN THE FOWL.

Before concluding this report upon frambœsia as it occurs in man, I have thought that a few words upon the disease as it occurs in the domestic fowl may not be unacceptable. The disease occurs as an epidemic among fowls in Ceylon and the West Indies, and probably in the other tropical countries as well, at certain seasons of the year,<sup>2</sup> generally from April to July or August. It bears a striking resemblance to the disease met with in the human subject in many particulars, but whether there is a causal relation or connection between the two diseases I am not in a position to state.

The disease in question consists of an eruption of yaws-like tubercles covered by a thin seal (resembling in appearance the yaws crust), very often showing points of hæmorrhage on its surface, just as in the case of the human subject. These tubercles are situated over the eyes, at the base of the beak, on the head and neck, around the ears, on the tips of and along the wings wherever there are few feathers, and on the legs. Young fowls and turkey chicks are chiefly affected, and death may occur, not from the disease itself, but from the inability of the birds to see and pick their food and their consequent starvation.

Plate XIX is a photograph of the head of a chicken with yaws. The eyelid is occupied by a tubercle; there is one over the ear and two or three immediately over the bill.

The points of resemblance to human yaws are the following, and I do not think I shall be going too far when I say that they are more than mere coincidences: (1) The tubercles bear a striking resemblance outwardly to those of the human subject. (2) The disease occurs on the most unprotected parts in both. (3) Young chickens are chiefly affected. I do not remember having seen the disease in full-grown fowls. In the human subject children are the principal sufferers. (4) There is similarity in the site of the eruption in the fowl to that in man. (5) A micrococcus, such as I have discovered in human yaws tubercles, is also seen scattered throughout those of the fowl. (6) A yaws tubercle from the lid of a fowl was excised, and a sterile tube of nutrient jelly was inoculated immediately with the blood that issued from the cut. In three days a grayish-colored cloudiness was seen in the track of the stab and the jelly was rendered slightly fluid on the surface. The turbidity was due to the presence of myriads of coccus forms, singly, in two's, and in small clusters. Their size was the same as the microbe of human yaws. About a week afterwards the growth assumed a pinkish tinge and

<sup>1</sup>It is worthy of remark that in the parangi disease of Ceylon, which is considered to be identical with yaws, a rise of temperature has been noted to precede an outbreak of the eruption. I quote from page 75 of the Report upon the Parangi Disease of Ceylon, by Mr. W. Kynsey, principal civil medical officer: "Fever occurs; in some instances it is very severe in character (the temperature being 99°, and sometimes rising as high as 100° or 102° in the evening); it is comparatively slight in others. The fever is attended with constitutional disturbance; it remains for about two or three days, when a crop of eruptions, papular in character, appear about the different parts of the body beginning at the face and gradually extending downwards; these papules vary in size from that of a peppercorn upward." Again, on page 46, Mr. Garvin says: "Just as the sore was healing [the sore Mr. Garvin mentions was the seat of inoculation of the parangi disease] he got what he considers an attack of fever, attended with pain in the large joints and back. This attack went on for about four days and then subsided, but on the third day following he observed the eruption coming out on the right side of the neck first and then over the body." The same medical officer observes, on page 45 of the report: "A crop of eruption appeared on the face, preceded by slight fever, loss of appetite, malaise, and pains in the large joints for a day or two." *Vide.* also in Appendix, Case CXXVIII, where a febrile condition is reported as having occurred previous to the appearance of the eruption.

<sup>2</sup>The negroes say when the cashew fruit (*Anacardium occidentale*) is ripe.

the jelly became more diffuent. These appearances then are identical with those presented by the microbe of human yaws. (7) Lastly, a vertical section of a frambœsia tubercle in the fowl presents the same anatomical appearances as those already described in the case of man; that is to say, enlargement and growth of papillæ, proliferation of cells, and protrusion of new vascular growth upward through the epidermis.

Plate XX a vertical section of a yaws tubercle from the fowl. Logwood staining. Leitz, Oc. 2, Obj. 3: ( $\alpha$ ) Enlarged papillæ; ( $\beta$ ) delicate strands of fibrous tissue; ( $\gamma$ ) blood vessels (cut); ( $\delta$ ) protrusion of organized tissue externally; ( $\epsilon$ ) areolar tissue. (The proliferation of cells well marked, but their outlines are somewhat overtinted in the diagram.)

The disorder is easily cured by isolation of the affected birds and their careful feeding, together with the external application to the tubercles of tincture of iodine.

I may say that an attempt at producing the disease in a chicken by inoculating it under the wing with the artificial culture of the micrococcus from a diseased bird proved ineffectual.

## APPENDIX.

ADDRESS OF THE PRESIDENT OF THE SECTION, C. H. HUGHES,  
M. D., ST. LOUIS, MO.

NEUROLOGY AND PSYCHIATRY OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS.

COLLEAGUES OF THE CONTINENT: I bid you cordial welcome. For the first time in the history of the world the medical profession of all the Americas meets fraternally for mutual work and words of counsel for the welfare of the North and South American medical profession and people. In this neurologic and psychiatric section, brothers, we also, for the first time, grasp the hand of fellowship. We heartily clasp hands with you and in our hearts we embrace you, with the prayer that nothing shall ever dissever the friendship between the Northern and Southern American profession now so auspiciously consummated. May the final hand shake between the profession of the North and South American States never be permitted to take place. We want your friendship forever. So long as "earth grows a plant or sea rolls a wave" we pray that it may endure, growing closer and closer in ties of inseparable fraternity. In our special departments of medical research and labor we have a common interest, and in every department of medical investigation and advance our interests are likewise mutual. The sanitary welfare of all of the American States is alike. The same hygienic, therapeutic and pathologic problems press upon us all for solution; the medical discoveries of each one of these States redound to the welfare of all the others. To this end, therefore, we salute and welcome you, wishing you health and happiness, through a mutually advanced and glorified medical profession, and in behalf of the neurological section of this great congress I join you in the sentiment, "*America laudamus—viva Americana!*"

Before proceeding to the work before us it may prove a source of pleasure and profit, and it certainly is flattering to our professional pride, to note some of the neurological advances of our day, and especially the contributions of neurology to general medicine and the consequent welfare of the world. None of the many victories in the onward march of American medicine during the century now nearing its close has contributed, or is destined yet to contribute, more to the happiness of mankind than the light which has been thrown by our researches on the nature and treatment of inebriety, dipsomania, and chronic alcoholism and their neural sequelæ, especially multiple neuritis.

To a distinguished American physician, signer of that Declaration which gave a nation birth, surgeon-general of the Continental Army and teacher of the practice of medicine in the first medical university founded in America, Dr. Benjamin Rush, the scientific world is indebted for having taught that inebriety is a disease. His followers, living in the Pan-American States, taking their cue from this distinguished pioneer medical *savant*, have pursued the study until the therapeutics of inebriety has become as successful as that of any other grave nervous disorder and its pathology as well understood, while medical philanthropy, following his advice,<sup>1</sup> has erected hospitals for the cure and care of its unfortunate victims, though, as yet, no monumental shaft mementoes, as it should, a nation's grateful memory of Benjamin Rush's noble work.

We record, also, with satisfaction scarcely exceeded by that we enjoy from contemplating the salvation of the inebriate the successful cure of the opium habit and other kindred forms of baneful drug enslavement. Yet it has not been long since that once brilliant litterateur, De Quincey, himself enthralled, proclaimed in despair the "pangs of opium" and the "Iliad of woes" its enslaved victims hopelessly endured. The "opium fiend," as he is with cruel facetiousness so often called, need not be longer regarded as a hopeless wreck if the hand of charity will

<sup>1</sup> Diseases of the Mind, 1812.

only conduct him within the pale of professional resource. This and alcoholism, and all similar forms of nervous derangement, are now treated successfully much like certain forms of mental aberration are; by change of environment, by therapeutic repression, including hypnotic support and reconstruction of the damaged and aberrantly acting neuropsychic centers. This is another jewel medicine offers for the crown of modern progress.

Notwithstanding the illustrious names which in our own day the world beyond our geographical boundaries has given to medical science, our American States have likewise their great physicians whose offerings on the altar of that science whose special care is the welfare of man are worthy of exalted place beside the Old World's gods. For the Virchows, Charcots, and Lombrosos, Maraglianos and Kowalewskys, Gulls and Horsleys, of world-wide fame beyond our shores, we have given to the world our Brown-Séquard, who went from America to cosmopolitan fame; our Hammond, another pioneer American neurologist, whose books have been translated into all the languages of civilization; our Seguin likewise, and our Pepper, president of this congress and the peer of Sir William Gull, of Great Britain; and Ferran, whose preventive inoculations against cholera Asiatica called the medical world's attention anew to the grandeur of Spanish medicine. If Wigan could conjecture the duality of the mind from theoretical considerations and the general division of the brain into hemispheres, Brown-Séquard later, and at the time an American, proved it, and even my own feeble contribution on the "Duality of Action and Vicarious Functions of the Cerebral Lobes and Hemispheres,"<sup>1</sup> in 1873, might count for something, even though it emanated from a lunatic asylum in the valley of the Mississippi. If Hitzig, a German, and Ferrier, an Englishman, demonstrated and located motor centers in the cerebrums of the lower animals, Bartholow, an American, established by satisfactory physiological experiment their correspondence in the human brain.<sup>2</sup> If Victor Horsley and others first clinically applied the discovery of cerebral localization to surgical therapeutics for brain diseases, Prof. William Fuller, a Canadian anatomist and surgeon, first trephined the skull in a case of idiocy, an operation which has recently been heralded from abroad as a new surgical procedure. The author of this operation, now residing in this country, in Grand Rapids, Mich., is the designer from life of a series of brain sections and sectional casts, photographs, and models, some of which I now show you, which have not been excelled in Europe. Now that this operation of Dr. Fuller has come back to America with European approval as a European procedure, it is interesting to note the reception a part at least of the medical press of England gave the novel surgical procedure at its inception on this continent. The following extract from the London Doctor, a monthly review of British and foreign medical practice and literature, No. 1, Vol. IX, page 5, January 1, 1878, is appended as evidence that the case reported in this paper received at the time a wide publication:

Dr. Fuller, of Montreal, has, says the Canada Lancet, conceived the novel idea of trephining out portions of the skull of an idiot child of 2 years old, so as to allow the expansion of the brain. The idea is certainly novel, so far as we know, no surgeon having previously ventured to remove portions of the skull cap so as to allow the brain to expand. We sincerely hope this brilliant (!) experiment will not be repeated. How does Dr. Fuller propose to protect the exposed portions of brain should the brain protrude through the apertures he has made? According to latest advices Dr. Fuller contemplates removing another piece. We hope not.

Under the name of linear craniotomy, this operation has recently found decided approval both at home and abroad. Engel speaks enthusiastically of it even for dementia epileptica.

<sup>1</sup>American Journal of Insanity. Vol. XXXII, 1875.

<sup>2</sup>American Journal of the Medical Sciences.

If European surgery first exsects a stomach or a kidney, or cuts down upon and removes a stone from the bladder or gall cyst, American surgery, represented in the person of Ephraim McDowell, with a temerity that startles the conservatism of Europe, first cuts into that surgical *terra incognita*, the abdominal cavity and saves an imperiled human life by successfully removing an abdominal tumor, a feat common enough now, alas, all too frequently performed by novices lacking in mature surgical judgment. He and Battey, another American, led the way for the successful ovariectomies of Lawson Tait and his followers, and Marion Sims—God bless his gentle, precious memory—lays the foundation, by a peerless procedure on the female perineum, for the rescue of womanhood from untold misery. Marion Sims who, when asked to unsex a woman in whom there was other possibility of salvation, could say to Weir Mitchell, “Let us give her a reprieve; I never unsex a woman without a pang,” and the woman got well, as you and I know hundreds of others would, if permitted, without oöphorectomy. God bless Marion Sims.

As we are justly appreciative of the part which American skill has performed in the world's surgical advancement; as the recalling of the names and deeds of our Motts, Brainards, Popes and Stones, Physics, Grosses and Hodgens gives us pleasure; if we revere our Rushes and Woods as England does her Hunters, Sydenhams, and Gulls, so of our own American alienists and neurologists and their achievements, we are justly proud. The accomplished Isaac Ray and the gifted Amariah Brigham, Pliny Earle and Tyler, now no longer among us, and Van Dusen, the son of Michigan and a Kalamazoo asylum superintendent, whose essay on “Neurasthenia” preceded that of the classical work of Beard on Nervous Exhaustion—Beard who gave to the world a new disease, and gave it a new name, although the term “neurasthenia” was borrowed unknowingly from Van Dusen (*vide Alienist and Neurologist*, Vol. I., No. 4, 1880). Since these contributions appeared the subject of nervous exhaustion has become too common in the literature of this country and Europe to need further mention here.

There are three works of Dr. Hammond which have had much influence on neurology and medicine generally and these were accomplished during his service as surgeon-general on the active list of the U. S. Army. (1) The establishment of the Hospital for Injuries and Diseases of the Nervous System in Philadelphia, where the foundation of Dr. Weir Mitchell's most original work, “Wounds and Injuries of Nerves,” was laid, Dr. Mitchell having been placed in charge by Surgeon-General Hammond. (2) The establishment of the Army Medical Museum in Washington. (3) The origination of the Medical and Surgical History of the War of the Rebellion. These three things give our colleague just claim to distinction. I think the Hospital for Nervous Diseases was the first of its kind ever established in the world. Besides, our colleague wrote the first systematic Treatise on Diseases of the Nervous System in the English language, if not in any language.

If we look for new discovery and classification of disease, America has not been entirely wanting. For a long time Beard's claim was controverted abroad, afterwards neurasthenia was called “the American disease,” then “American nervousness,” till finally foreign writers recorded it among their people, even in far-off Russia, where Kowalewsky has written his classic book on the subject and given us due credit for our discovery. So in regard to Hammond's discovery of athetosis and mysophobia, and the coinage of these terms; and in regard to neurasthenia, I believe it is even now conceded that the original American claim<sup>1</sup> of general functional neurotrophia as the foundation of nervous exhaustion is universally admitted.

---

<sup>1</sup> *Vide Alienist and Neurologist*, Vol. III, No. 3, 1882.

Seguin, in his clinical lectures in 1890, first suggested the substitution of a mixture of chloral and bromide for simple bromide, in the treatment of idiopathic epilepsy, when certain indications are present, chloral being indicated when the bromides alone produce undue stupor and extremely severe acne; also in cases where psychic disorder follows the stoppage of the bromides. This practice has now become general. He first attempted to subdivide the symptomology of "cerebral hyperæmia" (of Hammond and others) into several new groups according to etiology, e. g., cases due to lithæmia, to feeble or diseased heart, and (a large group) to eye strain, etc. He also attempted to give the distinguishing clinical signs (New York Medical Journal, December, 1892) between cases of cerebral paræsthesia due to insufficiency of the interni and those due to insufficiency of the externi, and recommended the use of nux vomica and strychnine for weakness of the interni, and of belladonna, cannabis indica, and other mydriatics for weakness of the externi, these drugs to be used as tests for diagnosis, and also for continuous treatment. He contributed by autopsies and clinical cases to confirm the doctrine of cortical localization of functions, in respect to the visual center (cuneus in 1880, I think), the speech center (1868), and, in subsequent years, the facial, brachial, and pedal or crural, centers, and gave absolute post-mortem evidence in support of the idea that such centers exist. Besides Bartholow's communication the whole subject of cerebral localization has received additional light from the contributions of our Charles K. Mills, of M. Allen Starr, Eskridge, Spitzka, myself, and nearly every American neurologist, while the contributions of Spitzka to cerebral pathology, as those of Isaac Ott to cerebral physiology, have been justly acknowledged abroad. Seguin and Hammond early advocated, before anyone abroad, I think, the use of large doses of potassium iodide in syphilitic or non-syphilitic diseases of the nervous system, giving historical proof of its American origin (New York), and called it the "American method." Attempts have been lately made in Europe to ignore our great priority in this. S. and H. Seguin say they learned it from Van Buren and Draper in 1865-1867. I adopted this practice at the insane hospital at Fulton in 1867-1868.

It falls to the lot of but very few men to discover a really important thing and to cause a great forward step to be made in medical science. Most of us must be content with helping the good work of adding new facts of secondary importance, and trying to apply scientific methods to the treatment of disease. I think that in this sphere of secondary scientific usefulness American neurologists have made and are making good records. The clinical relation of absent patellar reflex to locomotor ataxia, though first shown by Westphal and Erb, was extensively studied by Seguin, Gray, myself, and others, and its relation to other diseases and the possibility of the knee jerk being naturally *nil* in some persons, was first shown in this country and acknowledged abroad,<sup>1</sup> so that the knee-jerk criteria of tabes dorsalis is a lost reflex, and lateral sclerosis and other states of an exaggerated reflex. I myself offered the first proof many years ago that it need not be present in apparently healthy individuals. One of those persons still lives and is free from any spinal or other nervous disease to this day. What is true as to elucidation of this reflex is equally true of the cremasteric and other reflexes. (*Vide* writings of Weir Mitchell and others.) The bulbo-cavernous reflex and the virile reflex, practically the same thing, were discovered and clinically elucidated about the same time in Europe and America.

The value of the cremasteric reflex has been studied by Weir Mitchell with the same thoroughness of elucidation as he has given to lesions of the peripheral nervous system generally; and Dr. John Ferguson, of Toronto, Canada, has also thrown new light upon the patellar reflex. (*Vide* "Remarks on some cases of Hemi-

<sup>1</sup> "Diagnostic Significance of Absent Patellar Reflex." *Alienist and Neurologist*, January, 1880; *St. Louis Medical and Surgical Journal*, February, 1879.

plegia," *Alienist and Neurologist*, January, 1892.) This subject has also lately been enriched in this country by Dr. F. X. Dercum, in a paper on "Optic Neuritis, Blindness, and the Knee Jerk in Cerebellar Disease," read before the American Neurological Society, July 25.

The important subject of rheumatism affecting the nervous system was embodied in the recent address of Dr. Henry M. Lyman before the American Neurological Association, and attention called to important clinical facts, especially affections of the sensory nervous system, not commonly recognized as associated with this disease. The gastralgias, enteralgias, cutaneous irritations, sensitive feet, and arthritic and cutaneous neuritides of rheumatism have often attracted my attention and have been to me an interesting clinical study, and much more is yet to be written on this important subject.

In the therapeutics of the nervous diseases, as well as in clinical description and pathology, to America belongs much credit for originality and efficiency of discovery and suggestion. Was it not in this country that the great Brown-Séquard first conceived and promulgated his famous treatment for epilepsy, which has done more than all preceding or subsequent therapeutics suggested for the alleviation of this grave malady?

All the now acknowledged virtues of *phytoacca decandra*, or poke root, except the property of phytoline to reduce corpulency, were brought to my attention through the thesis of a student candidate for graduation of the St. Louis Medical College, in 1859; and Dr. Bealle, an ingenious fellow-graduate from Texas, that same year, told in a thesis, which he entitled "Ups and Downs of a Texas Doctor," how he made a satisfactory flexible bougie out of green slippery-elm bark, how he employed a smooth green wheat straw for a catheter and the crushed potato bug mixed with lard as a satisfactory vessicant in lieu of cantharides, practices which I imitated myself while doing a general country practice in Missouri in 1859 and 1860, when I could do no better, and there is nothing much better for gentle dilatation in certain surgical emergencies than a smooth slippery-elm bougie. I could relate other instances of Western American surgical genius in the use of therapeutic expedients in pressing emergencies of practice were they strictly germane to our subject.

It would require the space of many hours to detail the remedial virtues of our South American flora, beginning with our well-known cinchona. (*Vide* paper on this subject by Dr. J. B. de Lacerda, a colleague of the present congress.) I suggested and used chloral hydrate per rectum in the treatment of convulsive affections, a method based on the West Riding Asylum practice in epilepsy, and used by me for arresting the convulsions of children and of the puerperal state.

Leonard Corning's method of local anæsthesia is original, and we justly claim the discovery and therapeutic application of general anæsthesia as American, Sir James Y. Simpson to the contrary notwithstanding. Copious ether douching for cephalo-spinal pain was practiced by myself thirty years ago. I was the first to employ capsicum, hot coffee and ammonia enemata to resuscitate from profound opium narcosis (*vide* Appendix), after failing with a battery. Kiernan was the next to follow the practice.

In the department of electrotherapy, especially in diseases of the nervous system, America stands well forward in therapeutic suggestion and resource. Beard and Rockwell and their followers in this country have done much in this line. It has been fully thirty years since I first employed the constant current for cerebral and other congestive states, not excepting ovaries and pelvis, and recommended it in gynecology, based on a prior recommendation of Legros and Onimus that it would reduce intrapelvic, sanguineous fluxes. It has been more than twenty years since I began the systematic employment of constant cephalic galvanizations for the cure of insomnia and the treatment of epilepsy, under the conviction that the

prominent symptomatology of both of these affections were dependent upon disorder of vasomotor control, which cephalic galvanizations tend to restore as the bromides do.

Dr. J. B. de Lacerda, of Rio de Janeiro, has offered to this section a paper on "The Condition of Hyperexcitability of the Phrenic Nerve in Beriberi," which is a real addition to the subject. In this connection I may properly mention Dr. Henry M. Lyman's book on Artificial Anæsthesia and Anæsthetics, Insomnia, and other Disorders of Sleep, as a valuable American contribution to these subjects.

We have done no markedly original work in hypnotism, but have some imitators of Charcot and others, as Charcot and his followers have, with professional applause, followed Braid, the professionally tabooed Manchester follower of Mesmer, the mountebank original.

Cataphoresis in neurotherapy has been considerably advanced in America by Corning, Peterson, and others, and likewise the hypodermic use of arsenic by Moyer; also the employment of antipyrin, acetanilid, and other coal-tar derivatives, by the last named and many others. (*Vide Appendix.*)

The therapeutics, as well as semiology, of insanity has been enriched by Jewell and Moyer in this country by treatment directed to the colon. (*Vide Appendix.*)

Nitroglycerin, or glonoin, was first suggested to the regular profession in 1876 and 1878 by Allen McLane Hamilton, before Murrell or others abroad had used it, for anæmic cerebral states and spasms of the cerebral arterioles. It was on this recommendation and the recommendation of nitrite of amyl for a similar purpose that I first employed the latter for the differential diagnosis of supposed hyperæmic from anæmic intracranial states. (*Vide editorial in Alienist and Neurologist, October, 1888.*)

A decidedly original and successful procedure in American surgical neurotherapy is that of pudic neurectomy as a remedy for masturbation, reported by Dr. J. S. Eastman in the Medical News of August 12 of this year. The nerve being more sensitive on this side, Dr. Eastman cut down upon the left pudic nerve, which he found hypertrophied, and removed 3 inches of it. The patient gained weight and was freed from this vice, which had existed from the sixth to the twenty-sixth year. She had been previously sutured in the labia, cauterized, oöphorectomized, and clitoridectomized without benefit.

Veratrum viride, one of the very best remedies I know of for sthenic states of high cerebral and pulmonary congestion, with full, bounding pulse and violent cardiac systole, that is better than the lancet in high-grade apoplexy and pneumonia, as it is fatal to opposite asthenic states of pulmonary inflammation and cerebral congestion, is a distinctly American remedy, and the practice of using it, as well as of abusing its use, is of American origin. It may sometimes well substitute the bromides in certain phases of neurotherapy. I have so employed it. But we must not further dwell specially on American original contributions to neurotherapy. We could not complete the subject in the limits of an ordinary duodecimo volume, while another volume of equal size would not record the real practical progress and unequaled elegance of American pharmacy as applied to our therapeutics.

In the direction of neurological originality and advance the work of our own distinguished Spanish-speaking secretary, Dr. M. G. Echeverria, must not be overlooked. Though his modesty has prevented him from publicly claiming his due reward of merit, his claims have not been overlooked by foreign sources of appreciation. His English publications, notably his great book on Epilepsy, although scarcely noticed by American authors, is much and favorably quoted by neurologists in Germany, England, and France. On their merit he was elected honorary member of the Medico-Psychological Society, of Paris, and of Great Britain and Ireland; also vice-president to the first *Congres International de Medecine Mentale*,

held in Paris in 1878, when he was called upon to preside on motion of the late Prof. Lasegue, after the sudden illness of Dr. Baillarger, chairman of the congress. So far as I know, Dr. Echeverria was the first physician in this country who, as professor of nervous and mental diseases, delivered didactic courses of lectures on this subject. This was in 1861, in the University Medical College of New York, while Seguin followed at the College of Physicians and Surgeons, in 1873. On his removal to New York from the National Hospital for the Paralyzed and Epileptic, in London, where he had occupied the position of resident assistant physician with Drs. Brown-Séquard and Ramskill as visiting physicians, he induced the commissioners of public charities and correction to establish the Hospital for Epileptics and Paralytics on Blackwell's Island, New York, under his chief direction, and to found a school for idiots on Randall's Island. Dr. E. Seguin, *pere*, Drs. Kerlin and Wilmarth, of Elwyn, in their literary and practical works as revealed in the pages of the *Alienist and Neurologist* (*vide* Appendix), together with Dr. Brown, of Barre, Mass., and the Wilburs have certainly done much creditable pioneer work with this class of defectives.

We may here remark, as facts of historical interest, that Dr. Echeverria was the first in America to perform excision of a large portion (2 inches) of the ulnar nerve at the elbow for the radical cure of epilepsy following upon traumatic injury. This operation was performed in 1865, assisted by Dr. J. H. Douglas. In 1869, in the presence of Prof. Boeck, of Christiania, and other physicians and students, he removed, at the hospital on Blackwell's Island, from the base of the second parietal convolution of an epileptic lad, the largest sanguineous clot (1½ inches long by three-fourths of an inch wide) ever extracted, to that time. This is another operation lately originated abroad. The conical fibrinous clot was deeply imbedded in the cerebral substance, and the patient directly recovered his lost intellectual faculties upon the successful operation. The case is reported in his "Clinical and Anatomico-pathological Researches on Epilepsy," and in a subsequent paper published in Paris in 1878 (*Lesigue's Archives Generale*), with the records of five similar cases from Dr. Echeverria's own practice, and one hundred and forty, mostly by American and English surgeons. This paper was written mainly to show how unwarranted was the risk of this procedure then ascribed to it by French surgeons. This distinguished neurologist, one of our colleagues to-day, and those I have named before him, will not be overlooked when a candid world enumerates the history of America's neurological benefactors. Worthy of special mention with the foregoing is our indefatigable coworker and colleague, Prof. Charles K. Mills, whom the University of Pennsylvania has so lately honored with its chair of mental and medico-legal medicine. His recent studies in "Lesions of the Superior Temporal Convolution," accurately locating the auditory center, his presentation of the subject of aphasia and other affections of speech in their medico-legal relations, and lesions of the cauda equina, are real advances that must be universally acknowledged, as are likewise the complications of multiple neuritis, and other papers which we present in the Appendix.

And now I name another star which shines in the neurological firmament of New York—a Starr emphatically spelled by his far-seeing parents with a double "r." Among the numerous recent contributions, besides his book on Brain Surgery (published by William Wood & Co., New York), he has given us a special study of "Local Anæsthesia as a Means of Diagnosis of Lesions of the Lower Spinal Cord" (*American Journal of Medical Science*, July, 1892); "The Cerebral Atrophies of Childhood, with Special Reference to Imbecility, Epilepsy, and Paralysis" (*New York Medical Record*, January, 1892); "Trephining for Hæmorrhage of the Brain Producing Aphasia; Recovery" (*Brain*, 1892); "Hemianalgesia Alternans" (*New York Medical Record*, February 11, 1893), and has thrown some new light on the subject of syringomyelia. (*Vide American Journal of Medical Sciences*, May, 1888.) His

book, "Familiar Forms of Nervous Disease," is a credit to any country. Other bright neurological stars are shining, and many have shone longer in the same scientific and humanitarian sky.

It is my impression that Ord's discovery of myxœdema, received its first clinical confirmation in this country, and McLane Hamilton, I think, furnished five of the earliest clinical proofs of its verity as a distinct disease. Hamilton first pointed out the neurogenesis of certain meningeal inflammations, and I have maintained and do yet maintain that hæmophilia is a vasomotor neurosis.

The *Alienist and Neurologist* (April, 1884, *et seq.*) early maintained that oöphorectomy was too often performed upon the mistaken assumption that the ovary originated nervous disease, whereas the reverse is the most common clinical fact. This is not only an original American claim, but it is now becoming a generally admitted fact both abroad and at home, and the latest and best article on this subject is by Dr. Hamilton, in a late number of the *New York Medical Journal*.

Another rising luminary of this field is Dr. Frederick Peterson, a reference to whose late contributions (*vide* the Appendix) will interest you and show some good spokes, at least, in the wheel of neurological progress. His recent papers on "Cataphoresis," his physiological experiments with magnetism at the Edison laboratory, and his joint papers with Sachs on "The Cerebral Palsies of Early Life" (*Journal of Nervous and Mental Diseases*, May, 1890), and other papers to be found in Appendix, are all valuable.

But the stars of this firmament are too many to be counted. Should we dwell long enough to attempt it, we should not during our hour get around the circle. There remains Sachs, who has translated Maynert's *Psychiatry* for us; Bert Wilder, the brain builder of Ithaca; A. Jacobi, the universal genius; Corning, already mentioned, whose book on *Brain Exhaustion* is a standard. There is also Dana, to whom we have already alluded, with Carter Gray, whose respective books are abreast of all neurological advance, and in every way creditable to American neurological science. E. N. Brill, Graeme M. Hammond, and Brown of the *Journal of Nervous and Mental Diseases*, also Ambrose L. Ranney and his standard text-books on *Nervous Diseases* and *Neurological Anatomy*, and George I. Stevens with his Belgian Academy prize essays on the "Occulo-neural Reflexes, and the Relation of Eye Strain to Nervous Diseases," whose first article on this subject appeared in the earlier numbers of my journal. Too many stars to classify and minutely describe, but they make a brilliant constellation. If we look back to Philadelphia we discover another neurological star that has escaped our gaze, Horatio C. Wood, whose treatise stands high, and yet another, Dr. A. H. P. Leuff, of neuro-anatomical fame, also Harrison Allen, and there is Wormly, too, of Philadelphia, who is not altogether without the pale, and James Hendrie Lloyd. Far to the southward are Joseph Jones and Sanford Chaille, of New Orleans, and Buckley, of the occidental metropolis.

And now, casting our eye to Baltimore, our vision falls on three luminaries, Miles, Osler, and Hurd, whose light has not shone in vain. There also shine Conrad, Reed, Berkley, Welch, and Halstead of Johns Hopkins Hospital. Skirting the sky northward we come to the Hartford constellation, Stearns and Crothers. The book of the former is devoted to practical psychiatry, the contributions of the latter to that important branch of psychiatry which, through Kerr, Mason, Wright, Crothers, and others, has made such rapid forward strides in the American as well as in the English study of inebriety. The subject of alcoholic trance has been almost exclusively an American neurological study, and Dr. Crothers has contributed more than any other American, perhaps, to make it plain. In the Appendix appears further evidences of American advance in this direction.

I had almost omitted to note the excellent series of articles by Dr. Frank G. Baker, professor of anatomy in the medical department of Georgetown University,

on "Recent Discoveries in the Nervous System," which have appeared in the New York Medical Journal during the current year, and which have been copied into my own journal, from which it appears, in the language of the writer, that all the ideas we have had concerning the development and interrelation of these structures must be revised. The entire nervous system must be reëxamined, the history of every ganglionic center must be traced.

As our vision ranges further, Boston, with its neurological and psychological savants, comes into view—Philip Coombs Knapp and his book on "Intracranial Tumors and Other Diagnoses," Putnam, Channing, Webber, Folsom, John E. Tyler, the departed alienist of Sommerville, and Oliver Wendell Holmes, the poet sage and anatomical and psychological savant of Harvard. The subject of "Arterial Tension in Neurasthenia" received some new light from Boston in 1888 (*vide* article on the subject by Webber, Boston Medical and Surgical Journal, May 3, 1888); likewise the subject of "Lead Paralysis as it Affects the Brain" (*vide* same source, October 29, 1891); also the "Condition of the Blood in Certain Mental States" (*vide idem*, March 24, 1892). The same journal for August 29, 1889, also contained some additional light on "Paramyoclonus Multiplex" and other peculiar forms of spasm, and in September of the same year, in same journal, page 277, this American writer throws additional light on the subject of "Cerebral Tumors and their Treatment."

As we continue our survey of the neurological heavens, we come to the constellation Chicago, with such bright, particular, neurological stars as Lyman, with his book on Practice; Kiernan, the polyglot, who has given us good papers on nearly every subject in neurology, and who has especially enriched the subject of morbid erotism in its clinical aspects in the United States; Moyer, the tireless; Paoli, Sanger Brown, Brower, Clevenger, Lydston, and their books; and Church, sadly remembering one bright luminary of these heavens now blotted out, whose light shone for a time upon our particular sky with effulgent luster, Dr. J. S. Jewell. He was a star of the first magnitude, a neurological Jewell of the first water, an indefatigable student, painstaking observer, and a writer of the highest ability. He blotted out his own bright life in the prime of his manhood by overzealous work in the cause he loved above his life. He founded and maintained, while he lived, the Journal of Nervous and Mental Diseases. And this reminds us that we should not omit most honorable mention, in this connection, of the name of Dr. Jewell's worthy and industrious coworker, Dr. H. M. Bannister, among the men of might near Chicago who have contributed to brighten her brilliant neurological sky. Hinde and Moyer have also contributed a paper to "Clonic Rhythmical Spasm of the Pronator Radii Teres" (Journal of American Medical Association, 1887); and Moyer alone has contributed the following additional papers: "Periodically Recurring Oculomotor Paralysis" (The Medical Record, 1887), being the first case described in this country; "Akinesia Algeria" (Medical Standard, 1893), being the sixth case reported and the second in this country, and "A Rare Occupation Neurosis" (Medical News, 1893). By his works ye shall know him. (*Vide* Appendix for much more than we have here noted.) Within almost a suburban radius of Chicago is McBride, of Milwaukee, and his Review of Insanity and Nervous Diseases, and Bannister, of Kankakee, and till lately Patterson, of Batavia, now deceased.

Modesty forbids my dwelling at length upon what St Louis has done for the advancement of neurology. We may recover from our modesty sufficiently to appear in the printed Appendix; however, I might briefly intimate that both Dr. Bremer and myself have within the past few years added something to the literature of "Astasia Abasia;" Fry to "Chorea;" Shaw to the subject of "Trephining for Brain Disease," and Bauduy to the "Study of Alcoholism and its Treatment." This is not all that we have done, but it were better that someone else, non-resident,

should record and comment on our work, and I may say again, as I have said before, *vide* Appendix.

Now, if we continue our survey, we find the sky of neuriatry and psychiatry is not dimmed as we approach the region of the apparently setting sun. On the contrary, bright stars illuminate the western heavens. See how Eskridge shines. He has contributed a valuable paper on "Nervo-Vascular Disturbances in Unacclimated Persons in Colorado" (*The Climatologist*, March, 1892), the important conclusion of which is for persons on going to the high altitudes of Colorado, especially for those who are nervous or who suffer from pulmonary trouble or cardiac weakness, to live comparatively quiet until they become accustomed to their changed environments. Likewise another on "Chorea in Relation to Climate, Especially the Climate of Colorado" (*Climatologist*, August, 1891). This study of the effect of the climate of Colorado on chorea shows but little, if any, modifying influence due to altitudes of 5,000 feet to 6,000 feet. Another exceedingly valuable and advance contribution to the literature is "Retro-Anterograde Amnesia, with Report of Two Cases" (*Alienist and Neurologist*, July, 1892). This is an exceedingly interesting subject, both from a psychological and medico-legal point of view. This is as far as we can go with Eskridge. But he has written much from his high standpoint in the Rocky Mountains, and all is in the line of advanced neurology. (*Vide* Appendix.) Next comes Howell T. Pershing, of Denver, who records five cases of "Preataxic Tabes Dorsalis with Optic Nerve Atrophy," in which there were marked atrophy of the optic nerves with little or no ataxia. He gives a statistical study of tabes, and shows that (as Walton and Gowers have recently claimed) the early occurrence of optic atrophy is in some way associated with an arrested development of the spinal symptoms. This fact modifies the ordinary rules of diagnosis and prognosis. He also records a case of "Jacksonian Epilepsy," with successful operation; no recurrence of the paroxysms more than a year after operation. Other articles by this writer are: "Language and Brain Disease" (*Popular Science Monthly*, October, 1892), and "Disseminated Sclerosis following Syphilis" (*International Clinics*, July, 1891). But we can not go further in this manner. If we went hence south to the City of Mexico, thence across the Gulf to New Orleans, thence north to St. Paul, and crossed the continent to San Francisco, we should find working neurologists contributing their quota to the world's neurological and psychological progress.

As I am about to conclude, the proceedings of the July meeting of the American Neurological Association have just appeared in the weekly medical press, and here are its notes of American neurological progress: Besides the president's address and Dr. Dercum's paper, to which I have referred, Dr. Smith Baker's paper on "Heterogeneous Personality;" Matthew Field's, on "Hospital Detention;" Frederick Peterson's, on "Temperature in General Paralysis of the Insane;" Joseph Collin's, on "Changes in the Spinal Cord in old Cases of Infantile Paralysis;" G. M. Hammond's, on "Progressive Muscular Atrophy;" C. L. Walton's "New Method of Reducing Dislocation of the Cervical Vertebrae;" Dana's "Acromegaly, Gigantism, and Facial Hemihypertrophy;" J. J. Putnam's "Thyroidectomy in the Treatment of Graves's Disease;" B. Sach's "Tabes and Syphilis;" Krauss's "New Pedodynamometer;" Drs. Lloyd and Reisman's joint communication on "Infectious Endocarditis with General Septicæmia and Multiple Neuritis;" C. L. Walton's "Tumor of the Angular Gyrus;" Dr. E. D. Fisher's "Autopsy and Report of Congenital Cerebral Hemiplegia;" C. K. Mills's "Lesion of the Thalamus and Internal Capsule;" Wharton Sinkler's "Tumor of the Optic Thalamus;" George J. Preston's paper on the "Localizing Value of Aphasia;" Leonard Weber's, on "Neurasthenia;" Krauss's "Case of Myxœdema, with Observations;" Philip Koombs Knapp's "Simulation in Traumatic Nervous Diseases;" and "The Microbic Origin of Chorea," by Dr. C. L. Dana, are all instructive, suggestive, and progressive in our depart-

ment. The proceedings of this favorite American society are becoming every year more and more valuable. They are indispensable to neurological advance. The neurological world would not march on to its manifest destiny to rule paramount in the world's medical thought without the original work of this great American society of distinguished neurologists. There were also papers read only by title before this body, the names of whose authors are also adequate warranty of worth. Among them, "The Genesis of Hallucination and Illusion," by H. A. Tomlinson, of St. Peter, Minn.; "The Diagnosis of General Paresis," by L. C. Gray, of New York; "Two Cases of Friedreich's Disease," by F. R. Fry, of St. Louis; "The Metapore or Foramen of Majendie in Man and in the Orang-Outang," by Burt G. Wilder; "The Relations of Chorea to Rheumatism," by C. Eugene Riggs, St. Paul; "Experiences in the Use of Testiculine and Cerebrine," by J. J. Putnam, Boston; "Paralysis after Surgical Operations," by V. P. Gibney, New York; "Traumatic Brachial Plexus Paralysis in Infants," by William Leszynsky, New York. If I should go on enumerating the work, present and recent, of American neurologists, it would develop acute cerebraesthesia. It would make you tired. I had almost forgotten to note the contributions of our hospitals for the insane to the pathology of mental diseases. I can not now go entirely over this vast subject. Besides what has been done at Utica, N. Y., and Middletown, Conn., with which you are familiar through the Journal of Insanity, you may not know that it has for a long time been the custom of Dr. J. W. Blackburn, the eminent pathologist of the Government Hospital for Insane, at Washington, to each year select a number of cases for special study as a pathological supplement to the annual reports of the Government Hospital for Insane. This and the making of nearly one hundred post-mortem examinations yearly, constitutes the work of this hospital, to which I also invite your attention in the Appendix. I had almost omitted James Hendrie Lloyd, of Philadelphia, and Theodore Diller, of Pittsburg. You see, America breeds and develops neurologists as the water breeds and develops fishes. The pabulum neurology feeds on is in the American people; their hustling, rushing habits, their business, professional, social, and political environment, and the numerous newspapers they read every morning before breakfast and every night before they forget to say their prayers; this moral, political, social, and business atmosphere of ambition and bustle tends to develop the strongly endowed, neurologically and psychologically, as it tends in the weakly endowed to the development of neuropathic conditions. It develops neurologists and psychologists to care for the neuropaths. It builds and it breaks the nervous system. It can not yet be said that we are a neuropathic people, though we are tending that way; but neurology is advancing with equal pace with neuropathic breakdown, and will, it is hoped, ultimately enlighten and save the people from their neuropathic sins.

---

APPENDIX.

Dr. M. Allen Starr :

Diagnosis and Operation for Three Tumors of the Brain (American Journal of Medical Sciences, April, 1893).

Dr. T. D. Crothers :

Law of Periodicity in Inebriety (*vide* Alienist and Neurologist, July, 1892), showing a uniformity in the drink impulse and the laws which regulate it.

Some New Studies of the Opium Disease, read before the Philadelphia County Medical Society, January, 1892, pointing out a neurotic diathesis and various conditions favoring this disease.

Are Inebriates Curable? read before the English Society for the Cure of Inebriety, June, 1892, proving the curability and the periodicity from further study in this direction.

Sanitary Side of the Drink Problem, read before the American Medical Association, June, 1892, discussing the sanitary dangers from neglect of control of inebriates.

Medical Jurisprudence in Inebriety (*vide* International Magazine, February, 1893); an argument to prove the need of new legislation for inebriates.

## Dr. T. D. Crothers—Continued.

American Inebriate Asylums, read before the American Medical Association, June, 1893, being a historical review of asylum treatment for inebriates.

Criminal Inebriates and Treatment, read before the Congress of Criminology, June, 1893.

## Dr. Frederick Peterson :

Homonymous Hemiopic Hallucinations (New York Medical Journal, August 30, 1890, and January 31, 1891); Disturbances of Sense of Taste after Amputations of Tongue (New York Medical Record, August 30, 1890), and his paper on Gyrospasm of the Head in Infants (Philadelphia Medical News, October 1, 1892), are especially interesting.

Three Cases of Acute Mania from Imbibing Carbon Bisulphide (Boston Medical and Surgical Journal, October, 1892), and upon Physiological Experiments with Magnetism at the Edison Laboratory (New York Medical Journal, December 31, 1892).

## Dr. Harold N. Moyer :

Relation of Insanity to Crime (Chicago Law Journal, 1889); The Hypodermic Use of Arsenic (Therapeutic Gazette, January 15, 1891); Differential Diagnosis of Uræmia and Epilepsy (Medical Mirror, 1891), and Nervous Sequelæ of Influenza (Medical Age, 1891). This and the papers of Mills and Gowers, and my own contribution (Alienist and Neurologist), all present new features of this disease and prove it to be a toxic neurosis.

## Pathological Work of the Government Hospital for the Insane :

Report of 1887, Supplement, illustrated: Report of post-mortem examinations in thirty-one cases of paralytic dementia, or general paralysis of the insane.

Report of 1888, Supplement: Table showing the post-mortem appearances of the kidneys in two hundred and sixty-three cases of mental disease, giving the age, occupation, nativity, mental disorder, and co-existing physical disease.

Report of 1889, Supplement, illustrated: Report of post-mortem examinations in twenty-nine cases of mental disease. Part I, Fifteen cases of general paralysis and three cases of acute organic dementia. Part II, Eight cases of acute mania and three cases of acute insanity with maniacal symptoms, dependent upon organic brain disease.

Report of 1890, Supplement, illustrated: Report of post-mortem examinations in thirty-nine cases of epileptic insanity. Part I, Twenty-two cases of chronic epileptic mania. Part II, Seventeen cases of chronic epileptic dementia.

Report of 1891, Supplement, illustrated: A study of nineteen cases of general paralysis of the insane.

Report of 1892, Supplement, illustrated: I, Synopsis of post-mortem examinations in seventy-three cases of mental disease in females, with special reference to the condition of the organs of generation. II, Condensed description of the tumors found in five hundred and forty-six autopsies in cases of mental disease in males.

## Dr. H. M. Lyman :

Treatment of Neuralgia (Western Medical Reporter, 1889).

Insanity Proceeding from the Colon (Alienist and Neurologist, 1889, and Journal American Medical Association).

Experts and Expert Testimony (Alienist and Neurologist, 1891).

Insomnia in an Infant, with Reflections on Pathological Sleeplessness (Alienist and Neurologist, July, 1892).

Note on Nervous Disturbances after Removal and Atrophy of Testicles (Alienist and Neurologist, January, 1893).

Remarks on Presentation of Diplomas to the Graduating Class of the Barnes Medical College (Alienist and Neurologist, April, 1893).

Aphasia or Aphasic Insanity, Which? A Medico-Legal Study (Journal of Insanity, January, 1879).

Dr. Chas. K. Mills :

Spinal Localization in its Practical Relations (Therapeutic Gazette, May and June, 1889).

Lesions of the Sacral and Lumbar Plexuses (Medical News, June 15, 1889)

Brain Specimens Chiefly Illustrating Localization (University Medical Magazine, November, 1889).

Lesions of the Cauda Equina (Medical News, March 1, 1890).

Hysteria (Keating's Cyclopedia of the Diseases of Children, Vol. iv, 1890).

Myotonia and Athetoid Spasm (International Clinics, April, 1891); also, Autopsy in a Case of Athetoid Spasm and Myotonia (Journal of Nervous and Mental Disease, December, 1891).

Lesions of the Superior Temporal Convolution Accurately Locating the Auditory Center (University Medical Magazine, November, 1891). [This we regard as the most valuable and recent advance of this important subject.]

Aphasia and Other Affections of Speech in their Medico-Legal Relations (Review of Insanity and Nervous Disease, September and December, 1891).

Articles on Apoplexy, Brain Tumor, Spinal Tumor, Meningitis, Cerebritis, and Neuritis (Hare's System of Practical Therapeutics, Vol. i, 1891).

The Nervous and Mental Phenomena and Sequelæ of Influenza (Transactions of the Philadelphia County Medical Society, January 13, 1892)

Multiple Neuritis and Some of its Complications (International Medical Magazine, February, 1892).

Neuritis and Myelitis and the Forms of Paralysis and Pseudo-Paralysis Following Labor (University Medical Magazine, May, 1893).

Dr. Peterson has contributed four papers on Electric Cataphoresis (New York Medical Journal, April 27, 1889, and October 15, 1890; the New York Medical Record, January 31, 1891, and the Philadelphia Times and Register, March 21, 1891). This subject has received special elucidation in this country and is receiving more. It is a growing theme

Dr. J. T. Eskridge :

Case of Fracture of the Twelfth Dorsal Vertebra, Followed by Injury to the Spinal and Sympathetic Nerve Supply of the Bowel in the Region of the Ileo-cæcal Valve: Intestinal Hæmorrhage and Death on the Seventh Day (Medical News, October 10 and 17, 1891). The interesting feature of the above case is indicated by the title, and consists in the accurate localization of the spinal and sympathetic nerve supply to that portion of the bowel in the region of the ileo-cæcal valve.

Gunshot Wound of the Left Cuneus, with Right Homonymous Hemianopsia (*Ibid*, October 17, 1891). The case, which was carefully studied during the life of the patient, and the lesion accurately examined after death, which occurred a few days after the receipt of the injury, is another proof, if one were needed, of the relation of the occipital lobes to vision.

Myelitis in a Case of Incipient Posterior Spinal Sclerosis (International Medical Magazine, April, 1892). This case is one of posterior spinal sclerosis, which had run a course of several years, when typical symptoms of acute myelitis developed, an extremely rare complication of this chronic affection of the cord.

Acute Myelitis Preceded by Acute Optic Neuritis (Journal of Nervous and Mental Disease, September, 1890). In the report of this interesting case the author gives a short abstract of a number of others somewhat similar to it. One curious feature of the one here reported and of one of Dreschfield's cases is, that the optic neuritis reached its height before the spinal symptoms became manifest.

Poliomyelitis with Perineuritis (New York Medical Journal, December 26, 1891) The chief interest in this case lies in the fact that neuritis complicates poliomyelitis, and is a more frequent complication than was formerly supposed.

Tumor of the Brain (Denver Medical Times, January, 1892). The main interest in this case is in the perverted tactile sense and abolished muscular sense early in the history of the disease, later in the restoration of tactile sense, but the muscular and localization senses remaining completely abolished. The author promises an interesting report when the case is finally put on record in the light of the autopsy.

Some Points in the Diagnosis and Nature of Certain Functional and Organic Nervous Diseases (Alienist and Neurologist, January, 1892). The first part of this paper is occupied with reports of cases illustrating a point in the differential diagnosis of organic spinal lesions from brain and peripheral affections, first brought to the attention of the medical profession by Dr. C. E. Beevor, of England. These cases support the claim of Dr. Beevor in that, by the careful study of the associated and isolated actions of the two parts of the great pectoral muscle, a spinal lesion may be diagnosticated or excluded in doubtful cases. The second part is taken up in a discussion of the subject of Uric Acidemia, so prominently and enthusiastically advocated by Dr. Haig, of London. While the author is far from laying great stress upon this condition in the production of headaches, etc., and its treatment by acids and salicylates, yet he believes there are a number of cases, which, if well selected, much good results by following out Haig's method of treatment.

Dr. J. T. Eskridge—Continued.

Ataxia (International Clinics, January, 1892). The subject which forms the title of this paper is treated of in a systematic manner, and well illustrated by several cases.

Syringomyelia (International Clinics, Vol. 1, second series). This is an elaborate and very thorough report of a case of this curious disease, and in the light of the report of a recent case by J. Hendrie Lloyd, of Philadelphia, with an autopsy, including microscopical sections of the cord, there can be but little doubt that the disease now can be positively diagnosed during life.

Report of Cases of Moral Imbecility, of the Opium Habit, and of Feigning, in which Forgery is the Offense Committed (Medical News, January 14, 1893). The cases form an interesting medico-legal study.

Traumatic Myelitis (Medical News, March 4, 1893). The report of this case of traumatic myelitis illustrates how thoroughly the cord may be disorganized by concussion of the spine without any injury directly to bones, membranes, or cord. The subject of spinal localization is considered at some length in the report.

Idiopathic Muscular Atrophy (Journal of Nervous and Mental Disease, April, 1893). The infrequency of this disease gives the report its chief interest. The diagnosis is between idiopathic muscular atrophy and muscular atrophy of spinal origin.

Chronic Meningo-Myelitis (Denver Medical Times, April, 1893). The case herein described illustrates the effect of trauma in lighting up latent syphilis.

Dr. Wm. Fuller :

Surgical Shock (Medical Record), Montreal, February, 1877; Physiology of Convulsions, June, 1876; Treatment of Meningitis, August, 1877, and A Case of Cerebral Tubercle, December, 1877. The ideas advanced in these papers were not in accordance with the teaching of the day. In December, 1878, he published a paper in the *Detroit Lancet* upon Exophthalmic Goitre, referring all the symptoms to pressure and interference with the function of important peripheral nerves rather than to centric or sympathetic disease. Trephining of the Skull in a Case of Idiocy, with Remarks, a paper read before the Medico-Chirurgical Society of Montreal.

Dr. Rohé :

Dr. Rohé, of Catonsville, Md., in inquiring into the relations existing between pelvic disease and psychical disturbances in women (Journal American Medical Association, September 24, 1890), points out the frequency with which bodily conditions influence mental states, and shows that a "torpid condition of the intestines, Bright's disease, putrefactive processes in the intestinal canal, etc., might give rise to melancholia and other disorders of the mental functions."

Dr. Frank R. Fry:

The Sensory Symptoms of Three Spinal Cord Cases (Alienist and Neurologist, July, 1893).

The Etiology and Treatment of Chorea (1886). An Analysis of New Cases of Chorea (1889).

Chorea in the Aged (1891).

On A Case of Chorea Attended with General Multiple Neuritis (1891).

On The Co-Existence of Chorea and Alien Spasmodic Phenomena (1892).

## PAPERS READ BEFORE THE SECTION.

### PARALYSIE SPASTIQUE CÉRÉBRALE DES ADULTES.

Par le Docteur M. CARMONA Y VALLE, Mexico.

MESSIEURS : La paralysie spinale spasmodique de Erb, ou tabes dorsal spasmodique de Charcot, est une affection qui ne figure que depuis peu de temps dans le cadre nosologique.

C'est en 1875 que ces deux auteurs crurent la découvrir et la rapportèrent à une sclérose primitive des cordons antéro-latéraux de la moelle. Depuis cette époque tous les traités spéciaux de pathologie la décrivent comme telle et dans toutes les cliniques on entendit parler de sclérose primitive des cordons antéro-latéraux de la moelle.

Malheureusement, l'anatomie pathologique n'est pas venue sanctionner ces vues purement théoriques, car dans aucune des autopsies faites jusqu'à ce jour, on n'a pu démontrer l'existence de la sclérose isolée du faisceau pyramidal. Tantôt on a trouvé de la sclérose en plaques, tantôt de la sclérose latérale amyotrophique, tantôt, enfin, de la myélite transversale ou en foyer.

Charcot lui-même, dans ses leçons de 1880, dit que jusqu'alors on n'avait pu prouver la dégénérescence primitive dans les prétendus cas de tabes dorsal spasmodiques.

Le Dr. Pierre Marie, dans ses belles leçons sur les maladies de la moelle, publiées l'an passé, propose de conserver la dénomination de tabes dorsal spasmodique autant pour rester fidèle à son maître Charcot que pour ne pas introduire de confusion dans le langage scientifique actuel ; mais cette dénomination ne s'appliquerait plus à la sclérose primitive du cordon pyramidal, mais à l'arrêt de développement de ce faisceau, consécutif avec accouchements prématurés, ou aux accouchements dystociques lorsque la tête a séjourné longtemps dans l'excavation. De sorte que le tabes spasmodique serait toujours une maladie congénitale, ne se développant jamais après la naissance.

Ce fut Heine qui parla le premier, en 1840, de la maladie ainsi comprise ; il la dénomma paraplégie spastique cérébrale, et plus tard Little l'étudia avec plus de soin et l'appela rigidité spastique congénitale des jambes. D'autre part, Benedikt décrit l'hémiplégie spastique infantile comme une maladie propre à la première enfance, caractérisée par l'apparition de phénomènes aigus d'origine cérébrale, auxquels succède une hémiplégie spastique plus ou moins marquée qui dure toute la vie. Les membres paralysés subissent un arrêt de développement, et il est très fréquent de voir ces enfants devenir plus tard épileptiques.

Strümpell incline à croire que cette maladie est due à l'inflammation de la substance grise des centres psycho-moteurs et l'appelle polio-encéphalite par analogie avec la polio-myélite des cornes antérieures. Hirt rapporte plusieurs cas de cette affection et lui refuse la dénomination proposée par Strümpell en se fondant sur ce fait que les autopsies ont montré que les lésions morbides ne sont pas limitées à la substance grise, mais qu'elles s'étendent aussi à la substance blanche. Cette opinion qui peut paraître très rationnelle perd cependant beaucoup de sa valeur quand on considère que le faisceau pyramidal (substance blanche) a son centre

trophique dans les cellules des centres psycho-moteurs. Par conséquent, si ces cellules sont détruites les fibres du faisceau pyramidal doivent s'atrophier et perdre leurs caractères normaux. En d'autres termes, la lésion de la substance blanche ne peut pas être primitive, mais, au contraire, consécutive à l'altération de la substance grise.

Quoi qu'il en soit, et pour en revenir à notre historique, nous pouvons admettre : 1° que la science possède actuellement des raisons très fortes pour mettre fortement en doute l'existence de la sclérose primitive des cordons antéro-latéraux ou du tabes spasmodique, tels que les décrivent en 1875 Erb et Charcot; 2° que l'on admet aujourd'hui que la paralysie spasmodique au sens rigoureux du mot reconnaît trois origines : (a) Une lésion médullaire seule, sclérose antéro-latérale amyotrophique; myélite transverse ou myélite en foyer; (b) Une lésion purement cérébrale, paraphlégie spastique cérébrale de Heine ou rigidité spastique congénitale des jambes de Little, et enfin l'hémiplégie spastique infantile de Benedikt.

Comme on le voit, on admet donc aujourd'hui que la paralysie spastique d'origine cérébrale est, ou bien congénitale et due à un arrêt de développement du faisceau pyramidal, ou bien encore une maladie acquise mais propre à la première enfance.

Je viens démontrer que la paralysie spastique d'origine cérébrale n'est pas une affection propre à la première enfance, mais qu'elle peut aussi survenir chez l'adulte.

*Observation 1.*—Docteur J. G., né à Mexico, âgé de 50 ans, marié, de bonne constitution et sobre. A la fin de l'année 1887 il opérait un malade qui portait des végétations sur la verge. Pendant l'opération faite sous le chloroforme le malade fit un mouvement brusque et une goutte de sang entra dans l'œil droit de l'opérateur. Il se forma en ce point un ulcère chancreux qui mit assez longtemps à disparaître. Le ganglion préauriculaire et ceux de la partie postérieure du cou devinrent volumineux et douloureux mais ne suppurèrent pas. Quelques mois après, il survint sur les membres une éruption que le malade qualifia d'ectyma; mais le Dr. Valenzuela, qui alors le soignait, m'a assuré que cette éruption était banale et qu'elle n'avait pas les caractères de syphilides.

Actuellement il n'y a aucune tache sur les membres, et nulle manifestation secondaire ne s'est montrée depuis.

Trois ans plus tard, en 1890, pendant qu'il se trouvait dans un village de l'État de Michoacan, J. G. eut une attaque de céphalalgie extrêmement intense, accompagnée de nausée et de vomissements fréquents, entièrement apyrétique et qui disparut au bout de quinze ou vingt jours sous l'influence d'un traitement iodo-mercuriel.

Peu de temps après, et de retour à Mexico, un jour qu'il se trouvait dans son cabinet de consultation, il remarqua qu'il balbutiait en parlant, que la plume lui tomba de la main; il se sentit faiblir et enfin il perdit connaissance. Il n'eut pas de convulsions, ne poussa pas de cri, ne se mordit pas la langue et au bout de quelque temps il put reprendre ses occupations; mais il sentit ses jambes faibles et éprouva des engourdissements dans les trois derniers doigts de la main droite et les deux premiers de la gauche. Tous ces symptômes disparurent en quelques heures sans laisser de traces. Des attaques semblables se répétèrent de temps en temps, mais il m'a été impossible de fixer leur nombre non plus que l'intervalle qui les a séparées. Entre les attaques, il éprouva des troubles du goût et de l'olfaction, des diplopies passagères, des sensations de vertige comme s'il était sur le point de tomber dans un précipice. Après une des attaques, il resta momentanément avec la bouche déviée d'un côté qu'il ne peut préciser. Après une autre, il devint hémiplégique du côté gauche, mais le mouvement revint promptement et le malade revint complètement à la santé.

Enfin, le 24 juin 1891 il éprouva l'attaque la plus forte qu'il ait jamais eue, celle qui l'a laissé dans l'état où on le voit aujourd'hui, et qui, il faut le noter, fut la dernière. La perte de connaissance dura cette fois plus de 24 heures, il y eut du trismus, aucun aliment ne peut être avalé. Quand il revint à lui, il était complètement paralysé; il ne pouvait mouvoir aucun de ses membres et le cou même était complètement immobile. La rigidité de son corps était telle que, parfois, il se croyait atteint de tétanos. Les lèvres, la langue, et les yeux étaient les seules parties du corps qu'il pouvait mouvoir librement; la parole et la déglutition étaient normales. La respiration était difficile, mais cette difficulté ne provenait pas de la paralysie du diaphragme ou des muscles respiratoires du thorax, elle

était due à la rigidité, à la contracture des membres supérieurs. Les avant-bras en flexion forcée sur les bras et les mains sur les avant-bras comprimaient si fortement le thorax que souvent il pensait suffoquer. Il avait perdu complètement la notion de la position de ses membres; parfois il croyait avoir ses jambes en l'air et il fallait qu'une personne les lui touchât pour qu'il se rendît compte de leur véritable position. Malgré cela, il sentait les mains qui le touchaient, les piqûres de puces et les changements de température. Au début, il perdait les urines et les excréments sans en avoir conscience; mais peu à peu son état s'est amélioré, le sentiment de ces besoins naturels est revenu, mais de temps à autre il n'a pas la force suffisante pour retenir ses urines.

Je vis ce malade au mois de juillet 1892, treize mois après la dernière attaque, et sa situation n'a pas changé sensiblement. Jamais, il est vrai, il n'a voulu s'astreindre à suivre d'une façon soutenue un traitement rationnel.

Je le trouvai couché dans son lit en position supine, le drap-de-lit le couvrait jusqu'au cou, les cheveux et la barbe extrêmement longs, plus gros que je ne l'avais connu, d'un coloris excellent, la face animée, la parole facile, mais se fatigant quand il parle beaucoup. Il mange admirablement, ses digestions sont normales, il ne souffre aucune douleur, et il affirme que sans sa paralysie il serait parfaitement bien.

Il rend un compte exact de toute sa maladie; on remarque cependant qu'il n'a pas noté ou qu'il a oublié les dates d'apparition ou le mode de succession de quelques uns des phénomènes les plus saillants de son mal.

Tout mouvement volontaire du cou, des bras, des jambes est impossible. En le décrouvant, on voit qu'il est complètement nu, ce qui vient de l'impossibilité où l'on est de remuer ses membres. Les bras et les avant-bras sont intimement unis à la cage thoracique, les avant-bras fléchis sur les bras, les mains sur les poignets, les doigts rapprochés sont en flexion légère, non déformés. La pression exagérée qu'au début de l'affection les membres supérieurs exerçaient sur le thorax et qui gênait la respiration n'existe plus, cependant il n'est pas encore possible de séparer les bras du tronc, ni d'étendre l'avant-bras sur le bras.

Le malade croit qu'il commence à mouvoir les doigts de la main droite, mais à l'examen on remarque un glissement si léger qu'on doute s'il est réel ou apparent. En employant une force suffisante, on arrive à vaincre en partie la contracture sans provoquer de douleur, mais il est absolument impossible de placer les bras dans leur position normale.

Les jambes sont en extension forcée, les pieds complètement étendus sur les jambes et en légère rotation en dedans, les deux jambes rapprochées avec une tendance marquée à l'adduction. Il est absolument impossible de fléchir le pied sur la jambe, et par conséquent de rechercher l'existence du phénomène du pied. En déployant une certaine force, on peut fléchir la jambe sur la cuisse et celle-ci sur le bassin. Dans cette position, le malade peut volontairement glisser le pied sur le matelas et étendre la jambe, mais le mouvement volontaire de flexion est impossible. Lorsqu'on fléchit les deux jambes du malade, il reste quelques instants dans cette position, mais tout d'un coup elles s'étendent d'une manière brusque et énergique.

Les muscles sont parfaitement bien développés et les membres des deux côtés symétriques. La sensibilité à la douleur et la sensibilité thermique sont normales. Quant à la sensibilité tactile, il existe quelque chose d'anormal, car bien que le malade sente parfaitement la main d'une personne qui le touche, cependant, il ne peut toujours définir si un corps est rude ou lisse et quand on le touche doucement avec un objet dont la température est à peu près celle de la peau, il ne se rend pas facilement compte de cette sensation.

La vue, l'ouïe, l'odorat et le goût sont parfaitement normaux.

Actuellement, en juin 1893, je sais que ce malade est dans le même état qu'il y a un an au moment où je l'observai.

Ce cas nous offre un exemple parfait et complet de paralysie spastique, tel que le décrit P. Marie dans le cas d'arrêt de développement du faisceau pyramidal. De plus, cette paralysie est survenue après des accidents cérébraux manifestes: vertiges, troubles de l'olfaction et du goût, diplopies, paralysie du facial, hémiplegie, pertes de connaissance, etc.

*Observation 2.*—Hôpital de Jésus, lit N<sup>o</sup>. 1, département réservé. José María Romero, âgé de 34 ans, de race indigène, prêtre du diocèse de Chilapa, de bonne constitution et d'antécédents irréprochables, entra à l'hôpital le 4 mai 1891.

Il raconte qu'il n'a eu comme maladies antérieures que les fièvres intermittentes et qu'il y a cinq ans, en 1886, il commença à remarquer qu'il se fatiguait facilement en marchant et que cette fatigue disparaissait par le repos. Une nuit il sentit des fourmillements dans le pied gauche, des soubresauts des tendons et de la rigidité de la jambe en marchant. Le jour suivant il éprouva des phénomènes

analogues dans la jambe droite. En marchant il traînait les pieds, les jambes lui tremblaient et il croyait marcher sur de la laine. Très peu de temps après il remarqua qu'il parlait avec difficulté; dans cet état il souffrit une violente céphalalgie et eut du délire, il croit qu'il a eu de la fièvre, mais il ne peut l'assurer car on n'a pas pris la température. On l'enferma dans une chambre et il ne recouvra conscience de lui-même qu'au bout de quinze jours. Il se trouva alors complètement paralysé et dans l'impossibilité de prononcer un seul mot. Il avait le cou rigide, il ne pouvait exécuter un seul mouvement ni avec les bras, ni avec les jambes; la déglutition était difficile au point qu'il ne pouvait avaler les liquides que très lentement; il perdait ses urines sans s'en apercevoir; la constipation était tenace.

Peu à peu il recouvre l'usage de la parole, mais il conserva une façon de parler que je décrirai plus tard. La perte involontaire de l'urine dura huit mois et cessa ensuite définitivement. Les mouvements du bras gauche revinrent peu à peu et ce membre quoique lourd, lui est aujourd'hui assez utile. Le bras droit s'est amélioré, mais ses mouvements sont très limités. Il y a une impotence complète des jambes et depuis cinq ans il n'a pu faire un pas. Il n'a jamais eu de nystagmus, ni de tremblements intentionnels dans son unique membre utile.

C'est un homme moyennement développé, mais non affaibli; son visage est animé et d'un coloris normal; il mange avec appétit et digère bien. Il passe ses journées couché dans son lit ou assis dans un fauteuil; pour changer de place il faut qu'un homme le porte, car depuis cinq ans il n'a fait que quelques mouvements limités. Les jambes sont en extension forcée, entièrement rigides et en adduction. Tous les muscles adducteurs sont en contraction et forment un relief notable. Quand le malade est couché, il peut quoique avec peine fléchir la jambe sur la cuisse et celle-ci sur le bassin, mais quand il veut se mettre sur pied, il survient une rigidité si forte qu'il doit y renoncer. Ce phénomène qui est constant chaque fois qu'il veut appuyer les pieds par terre survient aussi souvent quand il est couché. Plusieurs nuits, il est arrivé que ces spasmes ou convulsions toniques sont devenus si violents que, les pieds se trouvant appuyés au mur ou sur le fer du lit, le tronc a été repoussé avec tant de force que plusieurs fois le malade est tombé du lit.

Le bras droit est très lourd, sujet à des contractures et secousses fréquentes; les doigts sont en demi-flexion, le malade peut les mouvoir volontairement, mais avec beaucoup de difficulté. Le bras gauche a des mouvements plus faciles; bien qu'il soit légèrement rigide, est pourtant le membre le plus utile dont puisse faire usage ce pauvre malade.

Assis sur son fauteuil, devant une table, il peut écrire assez bien. Pour écrire, il place le bras droit sur la table et avec la main gauche il place la plume dans les doigts de la main droite qui sont en demi-flexion. Il écrit ainsi lentement mais assez lisiblement.

Les muscles répondent bien aux courants électriques; l'excitabilité électrique est cependant exagérée. Les réflexes tendineux sont extrêmement exagérés dans les deux membres inférieurs et dans le bras droit; ils le sont moins dans le bras gauche, mais toujours plus marqués que dans l'état normal.

La sensibilité dans toutes ses formes est normale.

La manière de parler de ce malade est très singulière. Il n'oublie aucune parole ni aucune nuance de la langue, mais à chaque instant, presque à chaque mot, il éprouve le besoin de s'arrêter et de faire une inspiration forcée; il ouvre la bouche et contracte énergiquement les muscles du cou et les inspireurs thoraciques. Ces mouvements ressemblent tout à fait aux inspirations ultimes des moribonds. On dirait que les muscles inspireurs participent au spasme si marqué des muscles des membres. Cette manière de parler rend les réponses du malade extrêmement lentes et causent de l'angoisse à la personne qui les écoute. Peu à peu apparurent les phénomènes du décubitus; il se forma des escarres dans tous les points saillants du corps. Le malade alla s'épuisant jusqu'à la mort qui survint au mois d'avril 1893, après 6 ans de souffrances.

Malheureusement quand ce prêtre mourut, j'étais malade, incapable de me rendre à l'hôpital; ses parents s'opposèrent à l'autopsie et l'on perdit ainsi une occasion de faire progresser quelque peu l'anatomie pathologique.

Ce travail deviendrait trop long, si je voulais, après chaque observation, me livrer à toutes les considérations que chaque cas comporterait. Qu'il me suffise pour cette fois de signaler le fait qu'après quelques phénomènes prodromiques, tels que faiblesse des jambes, soubresauts des tendons, fourmillements, etc., et peu après difficulté de la parole, tout à coup il survint des accidents cérébraux bien nets: céphalalgie intense, perte de connaissance, délire et peut-être de la fièvre.

Puis, le tableau change, et il reste une paralysie spastique peut-être plus étendue que celle de la précédente observation, car à la paralysie des quatre membres vint s'ajouter de la dysphagie et des troubles de la parole. En revanche, la paralysie du Dr. G—— a été plus complète et plus durable que dans le cas présent puisque ce prêtre recouvra en grande partie le mouvement du bras gauche et que le droit lui permettait, mais difficilement, d'écrire.

Les observations suivantes, recueillies à l'hôpital de Saint-André par mes élèves de la clinique de cinquième année, sont des cas où les malades plus heureux ont recouvré une grande partie de leurs mouvements. J'abrègerai ces observations pour ne pas sortir des limites de ce travail.

*Observation 3.*—Hôpital de Saint-André. Joseph Barragan, âgé de 28 ans, de constitution vigoureuse, entra à l'hôpital le 1<sup>er</sup> février 1892. Pas d'antécédents héréditaires; il a deux fils bien portants; il en a eu deux autres mort-nés; il a eu les fièvres éruptives propres à l'enfance et des fièvres intermittentes. Il avait 19 ans quand il devint soldat; un an après, il eut les premiers accidents de la syphilis, suivis de manifestations buccales et pharyngées; de douleurs rhumatoïdes et plus tard d'une exostose de la clavicule droite.

En 1888, à l'âge de 23 ans, il fit une chute de cheval, il tomba de côté et il assure que sans avoir reçu de coup à la tête, il resta cependant un peu étourdi; mais au bout de peu de temps, il put se relever et se remettre à cheval.

Huit jours après cet accident, il eut une grande dispute avec un de ses camarades et la nuit suivante en faisant son service il eut à supporter le froid et la pluie.

Cette nuit-là il éprouva une forte douleur dans toute la tête, qui, augmentant de plus en plus, l'obligea à se coucher. Le lendemain, aux premières heures du jour, il nota que sa jambe droite était très lourde, agitée de secousses et que peu à peu la parésie envahit le bras du même côté. Ensuite le mal gagna la face, la bouche se dévia, les yeux se tournèrent produisant de la diplopie. Le jour suivant l'hémiplégie était complète, il perdit la parole, mais pendant quelques heures seulement. Peu de temps après il put parler, mais la parole resta lente et difficile.

C'est dans cet état qu'il fut apporté à l'hôpital militaire où il resta deux mois soumis au traitement ioduré. Il en sortit parfaitement guéri.

Il quitta l'état militaire et prit le métier de charcutier qu'il exerça pendant deux ans et demi en parfait état de santé. Il y a sept mois, sans cause connue, l'attaque revint avec les mêmes caractères que la première fois. Mais cette fois il resta chez lui sans se soigner et le mal empira. La paralysie du côté droit devint plus complète et rapidement la jambe gauche fut envahie, la sensibilité restant complète. Dès le commencement les membres paralysés furent pris par des spasmes, et des rigidités musculaires apparurent à la partie interne des cuisses et postérieure des jambes. Les seuls symptômes qui ne tardèrent pas à disparaître, furent le strabisme et la déviation de la bouche; la parole est restée lente.

C'est dans cet état qu'il entra à l'hôpital Saint-André à la date mentionnée plus haut.

Quand nous l'examinâmes, il avait la paralysie spastique la mieux caractérisée des deux membres inférieurs et supérieurs droits. La paralysie était plus marquée aux membres inférieurs qu'aux supérieurs. Il ne pouvait se mettre sur pied, parce que lors qu'il voulait le faire, ses jambes devenaient rigides et tremblantes. Le bras droit était impotent, rigide et en demi-flexion; les doigts moitié fléchis étaient peu mobiles. Il ne pouvait saisir un objet qu'avec difficulté et alors le bras était pris de secousses. L'élève qui prenait cette observation qualifiait ces mouvements de tremblement intentionnel de la sclérose en plaques. Mais après examen il fut démontré que ces mouvements n'avaient pas le caractère de ce tremblement, mais que c'était plutôt la trépidation qui s'observe dans le cas d'exagération des réflexes tendineux. Pour ne pas me répéter je ne m'attarde pas à signaler les contractures exagérées des muscles adducteurs des extrémités inférieures, ni la position de ses extrémités, ni à détailler l'exagération de tous les réflexes tendineux dans chacun des membres affectés. Je dois cependant rapporter que le bras gauche, quoique un peu faible, jouissait de tous ses mouvements et que c'était le seul membre utile de ce pauvre malade.

Dans tous les membres malades l'excitabilité électrique était manifestement exagérée.

La sensibilité tactile, à la douleur, à la température était conservée; mais la sensibilité musculaire était quelque peu perversie. Il avait une conscience parfaite de la position de ses membres, mais il avait perdu la notion du poids et il lui était impossible de distinguer les poids plus ou moins lourds qu'on lui faisait supporter.

Ce malade resta à l'hôpital presque un an. Bien que légèrement amélioré, puis qu'il pouvait faire quelques pas avec beaucoup de difficulté, il sortit presque dans le même état où il était entré.

*Observation 4.*—Hôpital de Saint-André. Jean Caravantes, âgé de 30 ans, employé de chemin de fer, sans antécédents héréditaires, de condition moyenne, n'a jamais abusé des boissons alcooliques, n'a jamais eu d'affections vénériennes ou syphilitiques.

Il a eu une pneumonie et quelques autres maladies fébriles qu'il ne peut spécifier.

Le 24 avril 1890 il éprouva tout-à-coup une sensation de pesanteur dans l'épaule gauche qui l'obligea à s'incliner de ce côté et ensuite à s'asseoir. Ne se trouvant pas bien dans cette position, il dut se coucher. Ce malaise dura peu, mais depuis lors cet accident se répétait plusieurs fois par jour, et de plus il nota qu'à ces moments-là, la jambe gauche, extrêmement rigide, se plaçait en extension ce qui rendait la marche impossible. Il passa ainsi six jours avec ces attaques qui passaient et revenaient plusieurs fois par jour; le septième il sentit la même pesanteur à l'épaule droite, mais la jambe de ce côté ne devint pas raide. Le 4 mai il eut dans la matinée un frisson intense qui fut suivi d'une forte fièvre et de délire. Il passa ainsi tout le jour et toute la nuit, et en se réveillant le matin du 5, il se sentit si frais qu'il voulut se lever, mais à sa grande surprise, il ne put y arriver parce qu'il se trouva complètement paralysé des quatre membres. Non seulement il ne put s'asseoir, mais on dut le faire manger parce qu'il ne pouvait faire aucun mouvement. Trois jours après, il commença à sentir dans la jambe gauche des picotements qui étaient suivis de mouvements involontaires. Ces mêmes symptômes apparurent rapidement dans la jambe droite. Les bras qui étaient aussi le siège de mouvements involontaires les premiers jours, recouvrèrent rapidement leurs mouvements volontaires, mais les jambes restèrent impotentes. Quinze jours après l'attaque, il quitta le lit, et pour faire quelques pas il fut nécessaire que deux personnes le soutinssent; les jambes étaient rigides, et il traînait beaucoup les pieds en marchant. La sensibilité était normale.

Il resta dans cet état sans changement notable jusqu'au mois d'août, il perdit alors complètement le sommeil et eut dix jours d'insomnie absolue. Alors survinrent des convulsions générales et une perte absolue de la parole. Les convulsions générales s'arrêtaient de temps en temps, mais revenaient chaque demi-heure ou chaque heure au plus. Il resta dans cet état deux jours; le troisième, il perdit complètement connaissance et resta ainsi un certain nombre d'heures. Il revint à lui et peu à peu il recouvra l'usage de la parole de sorte que quinze jours après il se retrouva avec sa paralysie comme avant.

Au mois de septembre il eut une nouvelle attaque de convulsions générales, mais cette fois elles durèrent moins de temps et il n'eut ni troubles de la parole, ni perte de connaissance. Il resta chez lui sans autre accident que l'impossibilité de la marche et en février 1891 il entra à l'hôpital Saint-André. Nous pûmes alors observer la paralysie spastique la plus complète. Les jambes étaient rigides et en adduction. Si on levait une de ses jambes et si on la laissait tomber, elle se croisait avec celle du côté opposé; les réflexes tendineux étaient très exagérés; l'excitabilité électrique augmentée, les sphincters normaux; il existait un phénomène curieux qui révélait l'exagération de quelques réflexes cutanés. Si pendant la miction une des cuisses venait à toucher le vase, la sensation de froid provoquait l'arrêt de l'écoulement de l'urine et la miction ne pouvait continuer qu'au bout d'un certain temps et avec de grands efforts. En dehors de cet accident la miction s'exécutait bien. Quand le malade aidé de deux personnes se mettait sur pied, les jambes devenaient plus rigides et s'agitaient en mouvements trépidatoires; il traînait les pieds, faisait des pas très courts et le pied qu'il voulait avancer se croisait devant l'autre.

Les membres supérieurs jouissaient de tous leurs mouvements, et la sensibilité sous toutes ses formes était physiologique sur toute l'étendue de la peau.

On le soumit à l'usage de l'iodure de potassium et son état s'améliora peu à peu. Il commença à marcher à l'aide de roulettes, puis avec des béquilles et ensuite en s'appuyant sur une canne. Il sortit dans cet état de l'hôpital au mois d'août de la même année, et il resta ainsi jusqu'au 17 janvier 1892. Ce jour il eut des frissons intenses, suivis de fièvre et de douleurs aiguës dans la région lombaire. La fièvre dura quelques heures et cessa ensuite pour revenir le lendemain à 7 heures du matin et disparaître à 11 heures du matin.

Pour ce motif il revint à l'hôpital Saint-André. On lui donna un peu de quinine et la fièvre disparut rapidement. Il marchait alors avec un peu plus de difficulté que lorsqu'il sortit au mois d'août. On le soumit de nouveau au traitement ioduré, on lui donna du calomel jusqu'à production de gengivite légère, on lui mit des vésicatoires à la nuque.

A l'aide de ce traitement, il s'améliora peu à peu, jusqu'à pouvoir marcher sans canne ; mais il continua à ne pouvoir faire que des pas très courts, et il garda les jambes raides. C'est dans cet état qu'il sortit de l'hôpital Saint-André en novembre 1892.

En janvier 1893 il entra à l'hôpital de Jésus presque dans le même état que lorsqu'il était sorti de l'hôpital de Saint-André. Il suivit le même traitement que celui qu'on lui avait administré dans cet hôpital. Caravantes s'améliora un peu plus. Ses pas étaient un peu plus grands, mais les jambes restèrent rigides et en marchant c'est à peine s'il fléchissait les articulations du genou.

Au mois d'avril il sortit de l'hôpital de Jésus et depuis lors on le perdit de vue.

*Observation 5.*—Hôpital Saint-André. Augustin Barron, né à Veta-Grande, Zacatecas, âgé de 30 ans, commerçant. Pas d'affection du système nerveux chez ses ascendants. De bonne santé habituelle, mais a un peu abusé de l'alcool et des relations sexuelles. Il y a eu des accidents vénériens, mais pas de manifestations générales, et en effet on ne trouve ni pleiade ganglionnaire, ni vestiges dans la gorge ou sur la peau.

A la fin de décembre 1881, après un repas assez copieux, il se sentit indisposé de l'estomac, mais il y fit peu d'attention et se coucha. Il ne sait si dans la nuit il eut quelque attaque, mais le lendemain quand il se réveilla, il éprouva une douleur de tête extrêmement forte et vomit les aliments de la veille. De plus il était complètement paralysé et il ne pouvait mouvoir aucun de ses quatre membres. La bouche était déviée du côté droit, l'intelligence et la parole étaient normales. Il a été impossible d'obtenir des dates précises sur la marche qu'ont suivi ces accidents ; le malade assure cependant que les mouvements reparurent rapidement dans le côté droit et que le côté gauche resta paralysé plus longtemps, jusqu'à la moitié de février, où il se trouva bien portant et reprit ses occupations.

Il continua à abuser de l'alcool et du coït, quand en 1883 il eut une nouvelle attaque semblable à la précédente. Cette fois, cependant la céphalalgie fut beaucoup plus intense et durable ; les vomissements plus tenaces. La bouche ne fut pas déviée, mais la paralysie fut générale.

On le porta en voiture à Zacatecas et il se rappelle qu'en route il voyait les objets doubles. Arrivé à la ville, il reconnut les personnes qui le reçurent, mais quelques heures après il perdit entièrement conscience et ne revint à lui que deux mois après. Sa famille ne lui dit rien de ce qui s'était passé durant ce temps. Il sait seulement qu'on lui mit un vésicatoire sur le ventre et qu'on lui coupa les cheveux parce qu'il lui était venu une éruption à la tête. Quinze jours après avoir recouvré connaissance, il put commencer à se lever aidé de quelques personnes, car la perte absolue de mouvement dans la jambe gauche le mettait dans l'impossibilité absolue de marcher. La jambe et le bras droits jouissaient de tous leurs mouvements ; le bras gauche était faible mais les mouvements y étaient assez faciles ; seule la jambe de ce côté était complètement immobile.

Notre malade revint en voiture à sa ville natale et peu à peu les mouvements de la jambe gauche revinrent, jusqu'à la guérison complète.

Trois ans après, en 1886, il eut une autre attaque pareille aux précédentes, mais d'intensité et de durée moindres. Depuis cette date jusqu'en 1890, il eut quelques petites attaques, comme il les appelle, et qui consistent en une subite lourdeur de la jambe et du bras droits accompagnée de sensation de chaleur ou de froid, de fourmillements et surtout de rigidité et de soubresauts de tendons dans la jambe.

Ces symptômes duraient un ou deux jours et disparaissaient complètement.

Un jour de l'année 1890, il nota en se levant que ses mouvements étaient très difficiles et alors il résolut de se faire transporter à Aguas-Calientes pour y prendre les bains. Il y resta 8 jours et remarquant que son état ne s'améliorait pas, il revint à Veta-Grande, où un matin il se trouva complètement paralysé, ne pouvant mouvoir même la tête. Il resta dans cet état 8 jours, au bout desquels il recouvra peu à peu les mouvements du cou et des membres du côté droit. Plus tard il recouvra les mouvements du bras gauche, mais depuis lors jusqu'à la date du 20 avril 1892 il n'a pu marcher à cause de l'impotence complète de la jambe gauche. Il a noté que depuis lors ce membre est resté complètement rigide ; que cette rigidité diminue beaucoup quand il est couché ; dans cette position il peut fléchir la jambe et la mouvoir avec une certaine facilité ; mais aussitôt qu'il essaye de l'appuyer sur le sol, elle s'étend fortement, avec des secousses, et il lui est impossible de faire un seul pas. Fréquemment ces spasmes surviennent même lorsqu'il est couché.

Le bras gauche jouit de tous ses mouvements ; mais de temps en temps il devient rigide ; et quelquefois l'avant-bras s'est placé en extension forcée sur le bras ; le premier en pronation, le pouce en adduction et flexion, les autres doigts fléchis sur les précédents.

Le 20 avril 1892, jour de l'entrée de ce malade à l'hôpital, on constata qu'il jouit de toutes ses facultés. Il parle parfaitement bien, et il meut ses deux membres supérieurs et l'inférieur droit comme une personne bien portante.

Couché en position supine, il a la jambe gauche rigide et en extension et adduction; le pied en légère extension et les orteils fléchis; les tendons extenseurs des orteils font un grand relief sur le dos du pied. Les muscles de la partie interne de la cuisse sont en contraction et forment une saillie notable. Aucun mouvement anormal.

Si l'on demande au malade de fléchir la jambe, il peut le faire mais avec grande difficulté parce qu'il avait à lutter contre la contraction des muscles extenseurs de la jambe sur la cuisse. L'exécution du mouvement commandé permit de noter la prépondérance d'action des muscles adducteurs et du tibia antérieur, car le membre est porté en adduction et le bord externe du pied est plus élevé que le bord interne. L'expérience ne peut pas être recommencée, car le malade ne peut répéter le mouvement, la contracture des muscles extenseurs s'y opposant.

Après quelques moments de repos, Barron peut fléchir la jambe, l'étendre et la porter sans grande difficulté dans la direction qu'on lui indique. Mais on peut noter un phénomène bien curieux qui se répéta plusieurs fois. Si on lui demande de lever la jambe de dessus le matelas, il le fait facilement la première fois; mais si l'on fait répéter le mouvement plusieurs fois, l'élévation est chaque fois plus faible, jusqu'à l'impossibilité d'exécuter le mouvement.

Si on le fait mettre sur un pied, la jambe gauche se fixe en extension, devient rigide comme si elle était en bois; le malade se lève d'une pièce, incline le bassin vers la droite, traîne la plante du pied, fait un pas très court et dirige la pointe du pied en dedans. La contracture de cette jambe est si gênante pendant la marche que malgré que la paralysie soit limitée à ce membre, le malade a gardé le lit constamment pendant tout le temps qu'il est resté à l'hôpital.

Pour en finir avec ce malade, je dirai que la sensibilité au contact, à la douleur, à la chaleur, au froid, la sensibilité spéciale des organes des sens sont normales. L'excitabilité électrique dans le membre paralysé est exagérée, les réflexes tendineux sont augmentés, et enfin la sensibilité musculaire est légèrement diminuée quant à la notion du poids.

Ce malade est resté à l'hôpital près d'un an, et il a été impossible de modifier la paralysie de la jambe gauche. Plusieurs fois de légères contractures sont survenues dans la jambe droite avec exagération des réflexes tendineux. Ce dernier symptôme s'est présenté aussi au bras gauche. Trois ou quatre fois le malade s'est plaint d'une sensation de pesanteur dans l'épaule gauche, semblable à ce symptôme initial que présenta le malade de la précédente observation.

Ces cinq observations démontrent jusqu'à l'évidence: 1° Que chez l'adulte la paralysie spastique peut se présenter consécutivement à des phénomènes cérébraux plus ou moins graves; 2° Qu'habituellement après la disparition des phénomènes cérébraux, la paralysie apparaît plus étendue, mais qu'avec le temps un ou plusieurs membres peuvent reprendre leur intégrité; 3° Que la parole peut rester plus ou moins compromise, mais qu'en beaucoup de cas les malades parlent normalement, et qu'enfin les malades peuvent rester monoplégiques, diplégiques, triplégiques ou paralysés des quatre membres, tout à fait semblables alors aux enfants dont les faisceaux pyramidaux ont subi un arrêt de développement.

On pourrait largement discuter le siège, la nature et la pathogénie de cette affection, mais je ne le ferai pas pour ne pas allonger ce travail, et parce que ces questions seront facilement résolues quand on connaîtra l'anatomie pathologique de cette entité morbide.

## ON THE PROGNOSIS OF "RAILWAY SPINE."

By F. X. DERCUM, M. D., of Philadelphia, Pa.,

*Clinical Professor of Diseases of the Nervous System, Jefferson Medical College; Neurologist to Philadelphia Hospital.*

A question invariably asked the expert in suits for damages in cases of railway injuries is, "Will this patient recover? and, if so, how long in your judgment will it be before recovery takes place?" I know of no question put to expert witnesses which is, as a rule, more difficult to answer, and regarding which there is often

such a variance of opinions. My experience does not accord with those who claim that the symptoms in a given case disappear with the award for damages. That buoyancy and exaltation sometimes follow a successful issue of the trial, and that the symptoms of mental depression, so frequently present, disappear for a time at least, can not be denied. However, if the case be watched, it will be found that long after the trial, when its excitement has passed away, the ordinary symptoms of the case persist. I have often been asked as to what treatment I would recommend for a given case, and have merely been able to answer in a general way that rest, tonics, freedom from care, would produce favorable results in time; that if the patient could be submitted to a prolonged rest-cure possibly recovery might be assured, or might take place more rapidly. A lack of opportunity to test the latter method of treatment has heretofore prevented me from giving a more definite answer. Recently, however, the opportunity presented itself. In order that there should be no question regarding the character of the case; in order that there should be no doubt or quibble regarding simulation, or improper motives of any kind, I selected for the experiment a case typical in character and in which there was no suit for damages. Before relating it in detail I will pass briefly over the method of diagnosis pursued by myself in cases of this kind, and which I have already published in a paper upon "The Back in Railway Spine."<sup>1</sup> The underlying principle of the method is to exclude as far as possible simulation or exaggeration of symptoms by the patient.

As is well known, the vast majority of these cases suffer from injuries to the trunk, more especially to the back. It is the back to which our attention is almost always called, even when there are injuries to the head or injuries to the limbs. With the patient standing or, if too weak, seated with the trunk exposed and the back turned toward the physician, the following tests are applied: After a rapid glance at the position in which the back is held, at the relative amount of curvature, at the differences in level of the two shoulders, at the presence or absence of muscular tremors, the following tests are performed: First, palpation: The hand being placed slightly upon the back the patient may or may not shrink. This symptom of itself counts for very little. It may indicate either the presence of a genuine hyperæsthesia or of a disposition to simulation. If hyperæsthesia be present, it is probable that we will find hysteroid symptoms as we proceed to study the case. The symptom by itself, however, as already stated, is of little value. The second test is by pressure. This I divide into superficial and deep pressure. My method of applying superficial pressure is as follows: I pass the finger tips, or the palmar aspect of the thumb, gently down over the spinal column, being careful to exert but a slight degree of pressure. As is well known, this test elicits in certain cases a flinching or other reaction as though pain were experienced, especially when we press over an area in the lower cervical or mid-dorsal region, over the dorso-lumbar juncture, the lumbar region itself, or over the end of the coccyx. The significance of this symptom I will not dwell upon now, but it is one which we all know is very commonly found in neurasthenia, especially in that form known as spinal irritation, and also in hysteria when the latter affection complicates neurasthenia. The next test is deep pressure. I now press the palmar aspect of the thumb with some degree of force upon various regions of the spine, and also over the adjacent muscles and various other portions of the back. If deep-seated soreness be present, as I have before pointed out, the patient is apt to react less suddenly than he does if simply a tender spot is touched by superficial pressure, or if there be general hyperæsthesia of the back. The soreness, if present, elicited by deep pressure is also more diffuse, and instead of being found directly over the spine of the vertebræ is apt to be found diffused for some little distance over one or both sides, or it may be found over the muscles in various other por-

<sup>1</sup> American Journal of the Medical Sciences for September, 1891.

tions of the back. Another test which I occasionally employ is the test by percussion. It is one of the tests that I employ when no reaction results from deep or superficial pressure, and is performed by striking with a small rubber hammer, the patient lying upon his face, a number of very rapid, though not hard, blows over the spines of the vertebræ, the idea being to elicit pain not by force of the blows, but by the faint but decided jarring produced. We now come to the test by motion. This also consists of two portions; first, the test by voluntary motion; and second, the test by passive motion. The patient is first directed to bend forward, his back being toward the observer. The manner in which the act is performed, the amount of the motion, the stage in the act of which the patient complains of pain, the area to which this pain is referred, and finally the occurrence of muscular spasm or rigidity should be noted. Next the patient is requested to flex the trunk to the right or to the left, and here again the character of the motion and the action of the muscles is studied. If no symptoms be elicited, or if they be of doubtful character, the operator may forcibly flex the trunk to the right or to the left, the patient not being warned beforehand of what the operator is about to do. As a rule this test is unnecessary. However, the following test I regard as very important in certain cases. This is the test by forcible rotation. An assistant, kneeling before the patient, should firmly grasp the hips, while the operator, seizing the shoulders, should gently but firmly rotate the upper half of the trunk. If there be deep-seated soreness the patient will at once give signs of suffering. As I have before pointed out, this method of searching for pain is a powerful one and is only required in exceptional instances. Its special application and significance I will not pause to point out. Next comes the test by transmitted shock. This I have also previously described. It may be practiced in various ways. The patient standing as erect as possible, the operator places both hands with fingers interlocked upon the head of the patient, and then by a sudden downward pull sends an impulse through the spine. The amount of force exerted must be guided by the reaction of the patient. The spine may be so very sore that the reaction to even a slight impulse is excessive and needless suffering caused; a gentle pull should at first be given, and if no response is elicited a more forcible one may be made. If it be desired to eliminate the cervical portion of the spine from the problem, the patient may be seated and the impulse be transmitted through the shoulders. A third method is to direct the patient, if standing, to raise himself upon the toes and then to let himself fall back heavily upon the heels. This method is less valuable than the others, for a man with a very sore back can absolutely not be made to execute this test properly. At most it should be used as a confirmation of pain doubtfully elicited by other means. I will not spend time in alluding to the various expedients, like the "double touch," for detecting malingering, nor will I recite the general methods pursued in studying the various subjective symptoms present in these cases.

The above tests that I have rehearsed apply of course to the physical condition of the back only, and help us in the formation of an opinion as to whether there is or is not an injury to the vertebral column, ligaments, the muscles, or other structures. It is not, of course, necessary to detail here the methods pursued in searching for actual lesions of the spinal contents. In my own experience lesions of the spinal contents in "railway spine" are rare, and, furthermore, they were not present in the case which I am about to detail. The case is as follows (its early history was in part reported in the paper already alluded to):

B. W., aged 42, married, carpenter and builder by trade, presented himself at the University Hospital December 5, 1890. On the 17th of June of the same year, while erecting a barn, he had been struck by a large rafter in the middle of the back, knocking him down and pinning him to the earth. He was unconscious for a few minutes and later he was sick at his stomach. Vomiting recurred repeatedly during the next four days, the vomit occasionally containing blood. During this time he was not confined to the house, but continued outside directing his

men at their work. He said, however, that he felt giddy and was afraid to climb to a height. His back, too, felt quite sore. About a week after the accident he began to be troubled with headache, while the giddiness became more and more marked. The soreness now spread all along his spine. His physician, who accompanied him to the hospital, said that pressure upon the spine now made him sick at the stomach and also caused his face to flush. He was obliged to remain indoors; he was unable to collect his thoughts; could not concentrate his attention upon anything; slept badly at night; was restless and delirious. He had also become very weak. On stripping the man it was noticed that he held his back very stiffly, and, further, that there was a marked tremor apparently of all the muscles of the back. Lightly placing the hand upon the back caused flinching. Superficial pressure was now made over the vertebral spines. It was found that the patient flinched slightly as the thumb passed over the upper and the mid-dorsal regions. Deep and persistent pressure was next made on either side of the spinal gutter over the muscles of the small of the back and adjacent regions. The patient now reacted in such a manner as to convince us that these muscles were exquisitely sore. Tested by motion, it was found that the forward flexion, in fact movement in any direction, was accompanied by excessive pain; and, further, by an objective symptom of great value, namely, excessive spasm of the muscles. In consequence the movements were limited in extent. On attempting forcible flexion, spasm and pain were both grossly exaggerated. Transmitted shock elicited pain in the upper and mid-dorsal regions. The knee jerks were excessively exaggerated. Ankle clonus was present on both sides. There was also paroxysmal contraction of the tibialis anticus, sweating so excessive that it saturated his clothing, and there was also occasional flushing of the face. In addition, the patient presented various subjective nervous and mental symptoms suggestive both of hysteria and of neurasthenia. I learned afterwards from his wife that in August of 1890, some two months after the accident, he had had a convulsion. He had been growing steadily worse and less and less able to attend to his business. The convulsions came on at night and was repeated for a number of nights consecutively. They are described by the wife as follows: "The convulsions usually came on at midnight, lasting until about 6 o'clock the next morning. They consisted of a series of paroxysms which followed each other at intervals of from five to ten minutes. The patient seemed to be entirely conscious during them. He would throw out his arms, throw back his head, roll up his eyes, and stiffen his limbs. Toward morning he would fall asleep and would wake up all right again. He finally grew so bad that he remained in bed continuously for about two and a half weeks, and then went to bed, off and on, until his visit to the University. He was delirious nearly every night during this time. He would have spasms, talk very much about the accident, and seemed to be constantly afraid of falling and of being hurt."

From the physical examination it was evident that the man had had a severe injury to the back. This doubtless consisted of a bruising and wrenching of the muscles and the muscular insertions. From the excessive pain present upon flexion and also upon transmitted shock it is very probable that the ligaments of the spinal column had also been strained. In addition he was excessively neurasthenic, and beyond a doubt the convulsions so ably described by his wife were hysterical in character. The case was thus a mixture of physical and subjective or psychic symptoms, and it may be looked upon as an exact counterpart of cases which every day appear as claimants for damages from railway accidents. It therefore suggested itself as an excellent one in which to test the resources of the rest cure. However, neither opportunity nor the patient's means permitted the carrying out of my suggestion at this time. The man went home and spent his time in and out of bed, improving a little now and then in proportion as he remained in bed, and presenting at the end of another year little or no change. He was now, January 12, 1892, admitted under my care to the wards of the Orthopedic Hospital and Infirmary for Nervous Disease (Dr. Weir-Mitchell having kindly granted me the privilege of one of his beds). His condition at that time was as follows: General fibrillary tremor of the muscles of the back and to some extent of the muscles of the arms. This tremor slightly increased on voluntary motion. There was also present excessive sweating, the surface of the trunk being decidedly wet. The back was exceedingly sensitive to pressure in the upper and mid-dorsal regions. The muscles to either side the spinal gutter were very sore. Forward flexion of the trunk provoked muscular spasm most marked in erector spinæ group. Lateral flexion produced a similar spasm. Transmitted shock elicited pain in the upper and mid-dorsal regions. All reflexes were exaggerated. Station fairly good; no bladder or bowel symptoms. In addition there was present tremor of the hands and of the tongue. The hands were livid, moist,

and cold. His weight at the time of the accident was 147 pounds; he now weighed 129 pounds. He was, further, exceedingly weak, nervous, and depressed, and suffered greatly from insomnia. He complained also of dreaming of the accident over and over again, and dreamed constantly of falling off of buildings. His wife now told us that in September of 1891 he had a return of his convulsions, and it took at times several men to hold him; that he was conscious as the attacks were coming on and as they were passing off; that he talked a great deal about having lost a piece from his forehead, asking each person who came to see him to try to find it, as his mind would never be right again until it was found; that he also cried a great deal, complained greatly of headache, and talked continuously about putting himself out of the way.

At the time of his admission to the Orthopedic Hospital no symptoms of delirium presented themselves. The man was placed in bed absolutely at rest and absolute seclusion was practiced as regards his relatives and friends. Systematic diet, in which milk played a large part, was now adopted and massage instituted. Later on the slowly interrupted faradic current was also used. Improvement was very slow at first, no change being perceptible for several weeks. However, little by little, a gain in weight was observed, and hand-in-hand with this also an improvement in the neurasthenic and hysterical symptoms. The back, however, remained painful to a very great degree. In the first few weeks following his admission he had several hysterical convulsions; later on these ceased altogether. His general condition continued steadily to improve, but the deep-seated pain and soreness in the back persisting, the treatment was prolonged week after week and month after month, in the hope of finally subduing it. At length it began to yield, but did not leave him entirely. However, on June 25, 1892, after over five and a half months of rest in bed, he was discharged almost but not entirely well. His weight had increased from 129 pounds to 157½ pounds. At the time of discharge his condition was briefly as follows: No fibrillary tremors present anywhere, no tremors of the arms or hands or any part of the body. Could flex the trunk, but it was still somewhat stiff and slight pain was still present. Any attempt at marked flexion still evoked slight spasm of the muscles. Did not sweat while standing still, but slight exertion or even mental excitement brought it on. His nervousness had practically all disappeared. He slept well and no longer dreamed at night. He said that he felt now as though he could work; in fact, that he felt now for the first time since the accident like "pitching in." This certainly suggested a marked return of energy. I impressed upon him, however, the importance of not doing a full amount of work at once, but of keeping up a partial rest cure at home. He did so, but notwithstanding had a return of a number of mild hystero-epileptic seizures this spring. However, a letter, dated June 22, 1893, tells me that he is well, with the exception of a slight soreness in his back.

The above case I believe to be extremely valuable from a medico-legal point of view, not only because of the absence of all elements of litigation, but because it throws considerable light upon the prognosis in this class of cases. It will be observed that before the patient was placed under systematic treatment he failed to improve. He remained practically in an unchanged condition, and it was not until systematic and an unusually prolonged course of "rest-cure" treatment was instituted that improvement finally took place. This man, further, had every possible motive to get well. His business and family suffered greatly by his absence. His worry from this source was very great. However, he now tells me that he is again actively at work at his occupation of builder. I should add, though, that none of the manual work is done by himself.

In previous papers<sup>1</sup> I have described cases without litigation, in which little or no improvement occurred even after the lapse of years. The only case in which I have had an opportunity of testing the effects of treatment was one in which the back symptoms were similar though the hysterical symptoms were absent. In this case, although rest in bed, massage, and even a plaster jacket were at various times instituted, and the treatment extended variously over two years, little or no improvement ensued.

<sup>1</sup> "Remarks on Spinal Injuries," *Therapeutic Gazette*, May 15, 1889. "The Back in Railway Spine," *American Journal of Medical Sciences*, September, 1891.

However, it must be admitted that it had not been possible at any time to institute a systematic course of rest cure. I am strongly inclined, however, to believe that in this instance it would have availed but little, and would not have influenced the chronic character of the case.<sup>1</sup> There are, of course, many cases in which tremor and spasm of the muscles of the back are not present or are concealed by the superficial fat. In these flexion, deep pressure, and transmitted shock, nevertheless, demonstrate the injury to the muscle insertions, ligaments, and other structures.

We now consider in how far are we assisted by the experience I have detailed in answering the question, "Will the claimant recover; and, if so, how long will it be before he recovers?" I have sometimes answered this question by saying frankly that I did not know. I was then asked by the court to use my best judgment and say how long it would take under the most favorable conditions for the patient to recover. Under the most favorable conditions generally implies a method of treatment which is not in vogue in general hospitals, which is rarely carried out as it should be in private practice, and which it is difficult to obtain except at special hospitals. This, I think, should be made clear in the answer of the expert when he answers that under the most favorable conditions, that is, by prolonged rest cure, the patient will markedly improve in about six months, but that complete recovery, if it takes place at all, will not ensue for several years. It must be borne in mind, further, that there are some cases of such great severity that probably no improvement will take place under any conditions, and also that there are others again very much milder in whom improvement takes place rapidly. Of course the answers must be adapted to each case.

## JUDICIAL RECOGNITION OF IRRESPONSIBILITY IN ALCOHOLIC MENTAL DISEASE.

By NORMAN KERR, M. D., F. L. S.,

*Chairman of the British Medical Association Inebriates' Legislation Committee; President of the (British) Society for the Study of Inebriety; Consulting Physician to the Dalrymple Home.*

There was a time, not very long ago, when the plea on behalf of an accused that he was "mad through drink" when he committed the crime with which he was charged would have had a curt reception from a judge. Nor could this be wondered at. In the belief that drunkards were but willful sinners, delighting to get drunk, voluntarily drinking only to become intoxicated and glorying in their shame, nearly everyone agreed. Judges are made of the same clay as is ordinary human-kind, and it could not be expected that members of the legal profession would detect disease of the mind where even doctors saw only a moral vice. This state of things prevailed in every community as well as in Britain. In those "good old times" short and sharp was the shrift of the murderer, though he had previously been drunk for days or weeks or years, and had never had any intention of hurting anyone. The Grecian law was merciless in its dealing with this class of criminals, the convicted drunkard receiving, in Mitylene, under the law of Pittacus, a double punishment—one for the crime, another for the drunkenness. Probably because imbued with this tradition the great Sir Edward Coke declared that drunkenness aggravates a crime (Coke upon Littleton, 547 a). Since Coke's day there has gradually been effected a remarkable change in criminal practice. Hale in former times and Hawkins in our own day lay down that equal punishment follows a criminal act whether done in a state of sobriety or insobriety. (Hawkins, Pleas of the Crown, Chap. I, Section VI.)

<sup>1</sup> For a detailed report of this case reader is referred to the paper, "A Case of Railway Back," *Journal of Nervous and Mental Diseases*, 1892.

This drop from double to equal punishment was only one step forward in the improved and more humane as well as just advance in criminal jurisprudence. My highly esteemed friend, Mr. Clark Bell, has pointed out in that valuable magazine, the *Medico-Legal Journal*, and in the Proceedings of the (English) Society for the Study of Inebriety the striking development in this direction of American law and practice, a progress which has not been left far behind by the rulings of English judges and the pleadings by members of the British bar. Evidence is now freely received on the accused's state as to sobriety to determine the presence or absence, for example, of malice. In the case, tried before Lord Low at Glasgow in May, 1892, of a discharged army pensioner, who had with atrocious violence killed his female paramour, his lordship said that there had been no malice or deliberation, the intoxication having maddened the prisoner, which at once took the case out of the category of murder. A plea of guilty of culpable homicide was tendered and accepted, and the sentence of fifteen years' imprisonment passed. At the same circuit court a young girl was convicted of murdering her mother with a hatchet and other articles, both mother and daughter being drunk. A similar plea was allowed, Lord Young sentencing the drunken child-murderer to one year's imprisonment.

Among other advances has been the ruling of Mr. Justice Stephen (*Regina v. Davis*, Newcastle, April 27, 1881) that, though the immediate frenzy of intoxication does not absolve, any secondary disease producing mental unsoundness and resulting therefrom does. Accordingly we find that in many cases delirium tremens, characterized by Mr. Justice Stephen as a distinct and formed disease caused by drunkenness, has been held to be a valid plea for unaccountability. Let me refer just to a case or two. Lord Young (*Regina v. Short*, Glasgow high court, August, 1889) declined to send the case of a woman charged with killing her child by starvation and neglect while laboring under delirium tremens to the jury, on the ground that delirium tremens was a disease, and discharged the prisoner. Baron Pollock (*Regina v. Mountain*, Leeds, April, 1888) told the jury that heredity as affecting the capacity of a man to drink like other people around him, and inciting him while intoxicated to commit acts of violence, must be taken into account, as the last person to know his own weakness was the person himself. The prisoner was acquitted as insane. Chief Baron Palles (*Regina v. Mary R. Galway*, summer assizes, 1887) ruled that exhaustion through loss of sleep as a nurse, which in her enfeebled state caused alcohol to make her insane and was the cause of her killing the patient under the delusion that he was the devil, entitled her to acquittal. The prisoner was acquitted on the plea of insanity.

These eminent judges all thus recognized certain physically diseased mental states, affecting the power to drink with impunity as to the capacity to reason and know the nature of an act, as absolving from accountability. But Mr. Justice Day (*Regina v. Baines*, Lancaster, January, 1866) went still further when he laid down that "whatever the cause of the unconsciousness, a person not knowing the nature and quality of his acts is irresponsible for them."

In a recent case, that of a highly respected man with a history of paternal suicide after a drinking bout and a personal history of occasional epileptic fits, who had killed his daughter after a drinking paroxysm extending over four days, though he appeared to be sober at the time, the accused was acquitted as of unsound mind. The presiding judge, Mr. Justice Wright, held that though the immediate effect of intoxication had passed away there was evidently no criminal motive. The prisoner was on good terms with his daughter, and insanity seemed the only conceivable cause of the tragedy. This case was clearly a case of the post-paroxysmal mania of periodic inebriety. A still more recent case was that of a man tried before Lord Young at Glasgow on July 14, 1893, for shooting and killing another man, who happened to be in his room, while the former was laboring

under delusions due to alcohol. He had been drinking to excess for six months, but became sane after he had been kept from drink in prison for a week. He was acquitted on a successful plea of insanity, and ordered to be detained during Her Majesty's pleasure.

These with other cases show that the trend of modern criminal jurisprudence is in the direction of giving fair consideration to the mental state of accused inebriate persons, with a view to ascertaining how far they may have been responsible for their acts. Modern medical and pathological scientific investigation is day by day throwing a new and clearer light on many diseased brain conditions antecedent to, concurrent with, and consequent on inebriate indulgence of various kinds, gradually revealing that many intemperate criminals, who were formerly condemned as voluntarily guilty of deeds of violence and other breaches of the law, were really involuntary offenders. When skilled and reliable medical inquirers have come to a general conclusion as to these mind-clouding, consciousness-eclipsing brain states, the legal history of the past affords ample warrant for the hope that the bench and the bar will be found to be ready for the judicial recognition, in dealing with accused inebriates, of the latest discoveries of sound pathological and psychological research.

#### TREATMENT OF NERVOUS DISEASES IN SANITARIUMS.

By JAMES K. KING, M. D., Ph. D., of Glen Springs Sanitarium, Watkins, N. Y.

The purpose of this paper is not so much to advance new principles as to make clear and emphasize those already known, but not usually within the reach of the general or private practitioner. It is an established fact that chronic nervous diseases are the most difficult class to manage in private practice. I except in this statement, of course, mental diseases for which suitable institutions are now successfully established. If I am able to throw any new light on this complex subject, the object of this paper will be fully realized. It may be well at the very beginning of this discussion to say that in order to make clear some of the methods and combinations of treatment, as well as to explain some of the cases referred to hereafter, it will be necessary to make some personal references. Twenty years ago I began the study of nervous diseases under one of the most distinguished superintendents of the Northampton Asylum. The first ten years of my study and practice were chiefly given to brain and nervous diseases. A large majority of the cases that came under my care were women. In so many cases the real causes of the mental and nervous disturbances were found to be reflex that I was led to search deeply for the original as well as the exciting conditions, and to try many experiments for the relief of symptoms varying in their severity, all the way from mania and profound melancholia and malnutrition to insomnia, headache, and hysterical excitement. In the grosser pathological changes of the uterus, bladder, and liver the connections are easy to trace, but when the deviation from the normal condition is slight it requires a close study to detect the relaxation of reflex symptoms. From these studies and experiments, these failures and successes, I gradually evolved the idea that it would be wise to combine two dependent specialties, neurology and gynecology. I could get no light on the question of this duality of specialties, so I made an experimental trip to Europe. Convinced of its real and practical value, I gave up my work at the end of ten years and went abroad for two years of study, devoting my time to the development of the union of these two specialties, and since my return I have carried them along together with much satisfaction. I am free to admit, however, gentlemen, that I believe this system can be carried out much easier in a medical institution than outside in private practice.

Specialties can not be too highly esteemed and zealously encouraged. Specialties have elevated the practice of medicine from the routine and drudgery of empiricism up into the character and dignity of a science. While all this and much more is true, yet there is need for caution. Humanity is like the pendulum of a great clock; we swing to one extreme or the other, never stopping in the middle ground. I have often thought of this in watching and thinking of Galileo's Great Bronze Lamp as it swings to and fro in the majestic duomo at Pisa. It was and has been and will be so in all professions. It has been so in medicine. When the literature and lines of investigation became too extensive for the individual mind and time to master, then, born of necessity, specialties blossomed into life. There is now danger of going to the other extreme. There is danger that specialties will become too special. In the last three decades specialties have been like trees grafted into the old stock, and had their root and vitality in the training of the general practitioner, who became specialists afterwards. In other words, they were grafted in the top. The danger is now that men want to be specialists without any general training or experience. There are men who rather pride themselves on not knowing anything outside of their specialty.

Gentlemen, would it seem immodest or presuming for me, before proceeding further to speak of the appliances, methods, and treatment of nervous diseases, to make a suggestion? I will venture. I would suggest that we have swung too far; that specialists are too much divorced and should be brought into more intimate and vital relations with each other. I would advise that specialists become partners or have adjacent offices, or, where practical, combine certain special lines of work, that they may examine cases and study symptoms and watch closely results and methods of treatment together. I would have the neurologist and gynecologist, the abdominal and general surgeon, the obstetrician and pediatrician, etc., side by side. I am satisfied from the experience born of a busy practice, covering a period of eighteen years in the treatment of nervous diseases and diseases of women, that men will be far more successful in proportion as they work together along these lines. A carefully prepared record of 4,000 cases bears witness to the truthfulness of this statement. A long list of cases come up to illustrate these facts; cases that had gone to the best nerve specialists, and had the most thorough and scientific treatment for their nerve troubles, and had not improved. Why? Because most of the difficulties were reflex. These same cases had gone to the oculist, and by him had been sent to the gynecologist. At his skillful hands they had been thoroughly treated for the troubles which he found, were they extra or intramural, para or periuterine, ovarian or tubal. But still the patients did not improve. Why? The treatment stirred up the already overwrought brain and hyperæsthetic nervous system, and the headaches, insomnia, irritability, and other symptoms grew worse. Finally these patients become discouraged and go home. What is the trouble? Were not all these men skillful? No one will question that fact; there are none better. Where, then, is the defect? I venture to assert from clinical experience that if these same men could have been combined in one, or could have treated these patients' nerves, eyes, and pelvic troubles conjointly, and each watched the effect of the other's treatment from day to day, instead of having them by installments, every one of them would have gone home well. I will only cite one case, as time is limited.

Mrs. B. J., aged 42, mother of four children, youngest 10 years. Marked neurasthenia with melancholia, insomnia, gastric irritation, and severe headaches; uterine hyperæmia and prolapsus. She had been skillfully treated by the best neurologists and gynecologists abroad and at home, and had been through the hands of the best oculists. She had been treated separately by some of our best men in New York for two years continuously, and all the symptoms had increased. The melancholia had deepened until it had assumed a suicidal type. At this stage she came under my care. It was an almost hopeless case, for she had tried nearly everything in the way of remedies and rest, and had had a good deal of sanitarium

treatment. I undertook the case without much prospect of success. At first I shared the responsibility with a lady physician, but finally took entire charge. After some weeks of a carefully modified course of systematic treatment, during which I followed closely all the details, she improved to a certain point, and seemed to hold only what she had gained. Then came the question of repairing a very slight laceration, which every one had thought of little or no consequence. I had noticed, however, that pressure on the cicatrix produced some of the nervous symptoms. I determined to try the experiment. I repaired the laceration, and, although it was impossible to keep her quiet or even in bed, the result was good. Everything seemed to aid in her improvement, and she entirely recovered.

In this paper I will endeavor to state clearly the reasons why we believe that nervous diseases can be more successfully treated in sanitariums than in private practice.

First. We all recognize without demonstration that one of the most valuable remedial measures in the management of nervous troubles is change of location, even though the surrounding conditions be not materially improved, and the value of this change is increased in proportion to the merits of the environments. In the city of Philadelphia Dr. William B. Atkinson has found that convalescent patients receive great benefit in being moved from one part of the city to another. This is often practicable when their means and circumstances do not permit of a more decided change. I have made it a practice for years when patients were recovering from a severe illness to change them as soon as it was safe to another part of the house with conditions as different as possible; also when a patient has been very ill in a room to change the location and surroundings. I have always found benefit follow these changes. There are always, in our widely diversified climate, resorts where we can send our patients and secure satisfactory climatic conditions, but very often many of the elements necessary to success are wanting.

Second. In these days of improvement and progress in every line there is no department of science and knowledge pertaining to health and happiness that has made more solid advances than that which we might call medical hygiene. Able bodies of distinguished men are devoting their best energies to the advancement of the foundation principles upon which the preservation as well as the restoration of health, nay, even of life itself, rests, and their combined labors are being richly rewarded. When our Surgeon-General, backed by our Federal Government, establishes a post-graduate school largely to advance the study of military hygiene; when such men as Mr. Ernest Hart can unfold with mathematical precision the hygienic principles that hold the secrets of controlling the dreaded ravages of cholera; when hygiene is made a special feature of a distinguished medical gathering like this, and a publishing house like the University of Pennsylvania Press embodies among its journals one on hygiene we can not fail to be deeply impressed with the importance of the subject. In this day a sanitarium to be worthy of the name must not only be situated in a healthful and bracing climate, surrounded by beautiful and varied scenery, possessing a variety of woodland shade and sunshine and a diversity of entertainment, but in addition it must possess that, without which no sanitarium or private hospital is worthy of patronage, a system of drainage that is as near perfect as human skill can make it. Elevated situation is an essential feature in the accomplishment of this end. We do not yet begin to know how much disease has its root back in the mysterious and secret laboratories of sewer gas, and to have a real sanitary institution it must be free from these noxious influences.

Third. A sanitarium that will command our confidence must not only be pleasant in its surroundings, bracing in its atmosphere, diversified in its entertainments, and free from any taint of sewage poison, but it must also have a good table. By a good table I mean a generous, wholesome, well-cooked dietary. This is an absolute essential to the successful treatment of most diseases, and especially is it true of nervous diseases. How many of us have been disappointed in the

results we hoped for in sending our patients away for improvement. The location, the air and climate, the surroundings, and even the sanitary arrangements generally may have been good, but with food poorly selected, badly cooked, and unwholesome in every way, we find our patients have lost instead of gained. I need not waste time in telling this able body of physicians how necessary in treating nervous diseases is the question of nourishment. Many cases would recover with pleasant and healthful surroundings and proper nourishment without much medication, while the same cases would not improve materially, however favorable the other conditions might be, if the table was unwholesome.

Fourth. A fully equipped sanitarium should have good mineral springs for both internal and external use when possible, the reasons for which will appear later in this paper.

Fifth. A remedial institution of this kind, in order to do its best, should not only have pure and mineral waters, but it must have a complete system of baths, which can be readily adapted by skilled assistants to any pathological conditions that may arise. It must also be furnished with apparatus for giving every variety of electrical currents; also it must be provided with skilled assistants and machinery for giving all the forms of manipulations and movements, active and passive.

Sixth. A sanitarium may have all the many advantages we have mentioned, and yet be successful only in the class of cases likely to be improved by change and general hygienic surroundings. To be complete it must have something more. Sanitariums and health or sanitary resorts are often confounded. A sanitarium, to be worthy of the name and to maintain a high standard and hold the confidence of the profession and the patronage of the laity, must have, in addition to these sanitary appliances, an able corps of medical men.

I have thus far briefly stated the chief distinguishing features of a scientific sanitarium. There are many less important points that will occur to you from your own experience. Having reviewed the equipments necessary to a remedial institution doing the best work in the treatment of nervous diseases, we will now consider the methods of treatment.

In this list of methods of treatment I unhesitatingly place, first of all, opportunity. The opportunity of having constant supervision of the patient can hardly be overestimated. No one can begin to realize the value of this privilege who has not tried both private and institution methods of treatment. It is valuable in diagnosis. This would imply that in this age of scientific knowledge there were mistakes made. Yes, that is true. It is true in all diseases, but particularly in functional nervous diseases. We do not yet know or agree on the exact nature of hysteria. Many cases of hysteria have been treated for organic disease, and many cases of organic disease have been treated for hysteria. I recall a case in point: Mrs. I. J. H., case diagnosed by several of our best nerve specialists as hysteria, and was treated for years as hysteria. She finally died, and the autopsy revealed organic brain disease. We need all the help we can get in many obscure nervous diseases, not only to diagnose the disease sufficiently to name it, but what is often far more important, to be able to study closely and note the differences in individuality and idiosyncrasy and treat it successfully. Again this access to the patient frequently enables the physician and attendants to study the treatment and its effects clearly, and decide many points which could be settled in no other way. This opportunity of frequent observation not only enables the physician to employ a great variety and degree of intensity of treatments, remedies, etc., with perfect safety, but also to note carefully the beneficial results, and the changes needed. It may be said that the trained nurse, to a certain extent, supplies this deficiency. A moment's reflection shows that both the means and the opportunity for observation in this latter instance are very limited.

Electricity, subtle, mysterious, powerful, and yet of great utility as a remedial agent, needs no champion. It speaks for itself in the thunder and lightning. It whispers in a million voices at once over the nation. It breathes its messages beneath the ocean. It purifies vast bodies of water for human consumption. It makes wholesale slaughter of germs, the enemies of our race. It lights our homes, runs our trains, propels our street cars, lifts our elevators, in short, vitalizes our entire lives. Why should it be less potent in restoring degenerated bodies? It is not. Electricity, galvanic, faradic, and static, in all the variety of currents has taken its place in the front rank of therapeutic measures. No nerve specialist, gynecologist, or even general practitioner can afford to ignore its merits, or sacrifice its therapeutic value. That it must be a potent factor in the treatment of nervous diseases in sanitariums will be taken for granted. There are, however, three serious difficulties in the general use of electricity. (1) Expensiveness of the apparatus. (2) The difficulty of obtaining thoroughly trained assistants; for I take it that there are few gentlemen here who have time to apply it to more than some of the most important cases in their practice. I have had any amount of trouble in training physicians, both male and female, in the use of electric batteries and the Apostoli method of treatment. It requires a certain amount of practical skill. I know a non-professional woman who has acquired great skill and success. (3) Constant supervision. Two apparently identical cases with the same disease, be it hysteria, eczema, locomotor ataxia, or neurasthenia, are not affected in the same way by the same bath or treatment. Neither is an individual affected in the same way on different days. Constant supervision is the price of success.

The general consensus of opinion is strongly in favor of all the various methods of improving nutrition, the circulation, and the tone of the nervous system by massage, Swedish movements, and the endless variety of machinery for exercising, toning, and improving the nutrition of the whole body. Here again we are met by the same difficulties; we find in the use of electro-therapy the need of expert assistants and vigilant supervision. For instance, these measures are very effectual in relieving rheumatism, circulatory defects, and nervous troubles; and yet they must be most carefully administered, for if overdone they are liable to cause nervous excitement, insomnia, or an acute attack of rheumatism. While it is not necessary in the employment of drugs to have this constant observation, yet it is of special benefit in the use of many of the newer and more powerful drugs. No one will dispute the fact that these same lines of argument on the value of constant observation apply to the question of the remedial benefits to be derived from rest treatment. Originating in Sweden, or perhaps in the far East in remote times, it has had many modifications, and experience has furnished abundant proof that each case should be studied by itself and treated on its own merits, adapting the amount of rest, seclusion, and exercise to the strength and condition of each patient rather than following some routine system.

All I have said about the great value of and the difficulties in the way of the scientific and successful employment of these special remedial measures applies with equal or even greater force when we come to the use of hydro-therapy. I have purposely left this until the last that I might consider it more fully. Though long known and its real merits understood by a few, yet the general appreciation of the value of hydro-therapy has only been realized in the past few years. It is like the operation known as "symphyseotomy," which was highly esteemed and practiced in Italy for twenty years before other nations began to appreciate its value. It is the popular operation now. Such classic works as Dr. Baruch's on hydro-therapy put it on a scientific basis. In hydro-therapeutics we have a mighty power for good or harm, and to be used successfully it requires (1) extensive and complete apparatus; (2) skilled assistants; (3) careful and continuous supervision.

This opportunity to note closely the effect on each individual case multiplies greatly the exceptions to many of the established rules of practice. I have recently had two cases of eczema extending over more or less of the body. The established rule is to avoid water in most cases of eczema, at least in the acute form. These seemed to me to be suitable cases for baths. I tried them cautiously with frequent modifications. Both cases entirely recovered. One of the cases was complicated with diabetes and the amount of sugar was 21 grains to the ounce. The ordinary remedies were used in connection with baths. This latter case had been for months under two of the best physicians in Canada, who had applied the same line of remedies and applications without success. The other case had been in New York. In both I recognized a distinctly nervous element. I have said that a thoroughly equipped sanitarium or private hospital should have, if possible, some good mineral springs to supply the water both for external and internal use. The positive value of spring waters of merit is becoming more apparent to the profession every year. The relation of hydro-therapy to disease, more particularly nervous diseases, is a subject still in its infancy. There should be pure spring water free from any possible source of contamination. There should be, when possible, water for internal purposes, that is alterative, laxative, and diuretic. There is also great advantage in having an alkaline water for bathing to neutralize the acidity so often found in connection with nervous diseases and acting as an exciting cause. While these waters for bathing are an important element in treatment, yet an equally vital one is the use of them internally. In the successful management of nervous diseases a free use of water is an essential remedy. I would emphasize this statement. England's distinguished therapist, T. Lander Brunton, has dignified water with the title of a "remedy." Savants in other countries have recognized its value as a remedy. There are also eminent men in America who appreciate the high position it occupies in the treatment of this class of diseases. I might mention the illustrious names of Meigs, Seguin, Ranney, Leuf, and Salisbury. These and others have referred to the value of water in the treatment of nervous diseases, but, like many great truths, important discoveries, or beneficial operations, the facts have not been generally accepted or applied. I am under the strongest conviction that this fundamental principle in the treatment of a large class of nervous as well as other diseases is not understood by the general profession, and not at all appreciated by the laity. You may ask what have the laity to do with this subject. I answer, the laity are the subjects and they do the drinking, and unless we can impress upon their minds clearly the rationale of its use and value they will not employ it faithfully. Water is such a common remedy they will follow it for a little while and then drop it. And here is one of the special advantages of treating these cases in sanitariums and private hospitals where the means are at hand, where the importance can be impressed upon the patient frequently, and where constant supervision will detect any marked variation from directions. When we remember that over 70 per cent of the human body is composed of water, it is easy to see that with a deficiency of this element health can not be maintained, and without this essential element in sufficient quantity any deviation from health can not be corrected. We might as well expect to run an engine without steam, a fire without fuel, or a water-wheel without a mill race, as to expect the skin, the glands, the kidneys, in short, the human economy, to go on performing its daily functions, and either maintaining health or restoring it when defective, without an abundant supply of pure water, the largest constituent of the body. It is an established fact that the better the nerves are coated, other things being equal, the less irritable and more natural is the whole nervous system. I have been making experiments in chronic nervous diseases with the object of testing the remedial value of the

internal use of water, either pure or medicinal, according to the associated conditions. These experiments include 400 carefully tabulated cases, aside from many more cases of which no complete record was kept. These experiments extend over a period of ten years. My plan was to take two sets of ten patients each, as nearly alike as possible, then to give each set of cases the most careful and approved care, making no change in the amount of water used by one set, but prescribing a marked increase in the amount of water drunk by the other set, and knowing that it was faithfully taken. The average increase in weight and general improvement in the set which used water freely was very much above that of the other set. These experiments were repeated so many times and with such care and close observation that there could be no question as to their scientific and intrinsic value. Definiteness and precision in prescribing and constant watchfulness in seeing that directions are carried out are essential to success. In the mystery of the value of water often lies the unexplained secret of the decided benefit frequently derived in nervous diseases, cystitis, and constipation from a sojourn at mineral springs, and during a course of rest treatment, in which large quantities of milk are employed. If you will describe to me a person who is nervous, who is irritable and out of sorts with the world generally, has dyspepsia and constipation, is sallow and has a bad taste in the mouth, has headache and does not sleep well, is troubled with bad dreams, often occupied in disposing of his relatives, has depression of spirits, is thin and has a hungry look, I will prove to you that such a man is a deficient water drinker. On the other hand, describe to me another man who is not nervous or irritable, who is in harmony with his environments, is good-natured and not a pessimist, has good digestion, does not have headache or constipation, who sleeps well and dreams little, and, if so, chiefly of angels and banquets, who is in good flesh and has the appearance of being well-fed; show me such a person and I can assure you, without further evidence, that he is a good water drinker.

I need not remind the members of this scientific body how often they have cases under their care which they know they could cure if they had the time and facilities for employing, under their own eye by trained assistants, more or less of the various means I have described in this paper, but it is quite impracticable in private practice. We all know what valuable aids to the efficacy of drugs, in the relief and cure of disease, are all these assistants; electro-therapy, hydro-therapy, massage manipulations, and mechanical appliances, rest and nutrition adapted to the needs of each individual case; but how are we to obtain them and, under what hygienic conditions are they calculated to insure satisfactory results? It seems to me, as the result of many years' experience, that it can only be done by combining in one plant all the necessary means, as in a private hospital or sanitarium. If the length of this paper permitted, it would be gratifying to add many clinical reports in support of the principles herein set forth, but as it is not I will close with one more point, viz: The value of moral treatment in nervous diseases in an institution with the facilities described. It is a settled fact that it is difficult and often impossible to say where nervousness ends and mental aberration begins. Dr. Hammond puts the per cent at five out of six in ordinary life. These border cases are most successfully treated in these institutions. This moral treatment is essential to recovery. It is necessary to prevent nervous persons from introspection, to provide occupation and diversion, to avoid their dwelling on and discussing their troubles, and to prevent their forming incorrect and exaggerated notions about themselves, and the relative value of their symptoms and treatment. I am certain, gentlemen, that these patients can be kept better balanced, can be lifted out of their fancies, and make much more rapid and permanent improvement when under these combined influences of occupation, variety of treatment, moral discipline and support, and constant supervision in a cheerful, home-like institution. I

have frequently tested these principles in private practice and under this combined method, and I fully believe that the day is not far distant when the private practitioner, the specialist, and the sanitarium staffs will be mutually helpful each to the other.

## ESTUDIO DE LAS CAUSAS, SÍNTOMAS Y TRATAMIENTO DE LA EPILEPSIA PARCIAL.

Por el Dr. ROQUE MACOUZET, de México.

*Médico del Hospital del Divino Salvador para Mujeres Dementes; del Consultorio de Beneficencia Pública, Segundo Secretario de la Sociedad Médica Pedro Escobedo, y miembro de la Sociedad Científica Antonio Alzate.*

Voy á ocupar un momento la atención de las respetables personas que forman la sección 18 del Congreso Pan Americano en algunas consideraciones á propósito de las causas, síntomas y tratamiento de la epilepsia parcial, deducidas de mis observaciones de algunos años en el Hospital del Divino Salvador para mujeres dementes del cual soy médico. Me concreto únicamente al estudio de la epilepsia parcial ó Jacksoniana, pues no obstante que las opiniones de las autoridades en la neuropatología no están enteramente de acuerdo en comprender en este grupo tales y cuales casos, ya en el transcurso de esta memoria se verá cual es mi opinión personal á este respecto, haciendo esto mejor que dar una definición difícil de que sea buena en asuntos de medicina y más difícil aún cuando de este ramo se trata.

De la estadística que hemos formado podemos deducir que las causas más frecuentes de epilepsia Jacksoniana son los tumores cerebrales (gliomas, sarcomas neuróglícos ó angiocolíticos, psamomas, carcinomas, y mixomas). Viene después la sífilis (gomas, osteomas etc.); los reblandecimientos inflamatorios, la meningitis, los traumatismos craneanos, los abscesos y hemorragias corticales, los tumores menígeos y craneanos, los tubérculos, y la atrofia cerebral. Estos resultados los hemos obtenido tanto de las autopsias que hemos verificado, así como del estudio que varios médicos mexicanos han emprendido, en la capital y en los Estados, de los cadáveres de individuos que presentaban esta enfermedad.

### SÍNTOMAS.

Para hacer un estudio metódico de los síntomas de la epilepsia Jacksoniana los dividiremos en dos grandes grupos: 1º, los de acceso, y 2º, los de los intervalos. Comenzaremos por estos últimos. Los síntomas que presenta el enfermo en los intervalos de los accesos son muy variados y los podemos clasificar en psíquicos sensitivos, motores, y tróficos.

*Psíquicos.*—Una de las cosas que más llaman la atención al hacer el estudio de esta clase de enfermos es la apatía intelectual. En casi todos los que hemos tenido oportunidad de observar, la memoria casi nula, al grado de olvidar algunos hasta su propio nombre, la atención excesivamente debilitada, lo mismo que la comprensión; otro tanto pudiéramos decir con respecto á las facultades afectivas. Este entorpecimiento intelectual se acentúa más después de los ataques. Generalmente son de carácter irascible. Algunas veces después del acceso les viene un sub-delirio tranquilo, aunque no es raro que les venga un verdadero acceso de manía aguda, como hemos observado en un caso. No son raras las alucinaciones de la vista y del oído; en algunos la aparición de figuras extravagantes, monstruos, fieras, etc., les anuncia el ataque, y en otros un ruido confuso y mal definido, un zumbido vago, una voz que balbucea frases incomprensibles en lengua extraña, un silbido. También hay alucinaciones del olfato, ya es el perfume de las flores, ya olores cáusticos ó pestilentes. También se suelen observar ilusiones.

La afasia en sus distintas formas se presenta á veces. Hemos observado un caso de sordera verbal representativa, en una Jacksoniana. A veces hay la ceguera verbal, pero esto es mucho más raro; otro tanto pudiéramos decir de la agrafia.

El vértigo es uno de los síntomas más constantes. Unas veces es el primero que se presenta y otras acompaña á los demás, ó aparece después que se hayan presentado.

Se observa en condiciones muy diferentes: ya se necesita que el enfermo haga movimientos muy fuertes y rápidos para que se produzca, ó bien basta el solo hecho de incorporarse en la cama, ponerse en pié, ó girar la cabeza; hay que notar que algunas veces este es el único síntoma de la enfermedad, sobre todo, el que se llama vértigo apoplético, en que el enfermo cae sin conocimiento, levantándose casi inmediatamente.

*Sensitivos.*—La cefalalgia es un síntoma tan frecuente como molesto. Es aguda, lancinante, persistiendo semanas enteras sin remisión; la impresión de la luz, los movimientos de la cabeza, el ruido, la inclinación del cuerpo, el simple esfuerzo de expiración, la exacerban y es tan fuerte, que á excepción de la uremia y de la meningitis, nunca se presenta con tal intensidad. Otras veces no es dolor propiamente dicho, sino una sensación de plenitud ó de vacío; ya les parece que traen en el interior del cráneo un cuerpo extraño que se les desaloja con los movimientos; ya que es un líquido viscoso que recorre lentamente toda la cavidad, ya al contrario muy fluido desalojándose entonces con rapidez; algunos se quejan de que les va á estallar la cabeza; tal es la sensación que experimentan.

No siempre está en relación el sitio del dolor con el de la lesión que lo produce; hay casos en que ocupa toda la cabeza; otras en sitio enteramente opuesto al que según los otros síntomas tiene la lesión, y no es raro que cambie de lugar. Sin embargo bien se comprende que haya casos en que coincida el lugar del tumor con el de la cefalalgia; así por ejemplo, un dolor tenazmente fijo en la región occipital, nos inclinaría á creer que el cerebelo fuera el sitio del padecimiento.

Por parte de la vista podemos señalar las moscas volantes, escotomas, congestiones, conjuntivitis muy tenaces, fusión purulenta del ojo, estrabismo, neuritis óptica, amaurosis lenta ó rápida en su producción, edema de la papila, hemorragia y atrofia de la misma. Ya se comprende cual deba ser el sitio de la lesión para que estos trastornos produzca, pero lo que no dejaremos pasar desapercibido es que estos son casi siempre bilaterales, no obstante que aquella generalmente sea unilateral. La explicación de esta paradoja es la siguiente: la decusación de los nervios ópticos no es completa en el quiasma, de manera que cada nervio tiene entre su origen y el punto de entrecruzamiento filetes que van á dar á los ojos, de suerte que basta que la lesión interese al nervio en este trayecto, aún dejando intactos los tubérculos cuadrigéminos y aun el mismo quiasma, para que los síntomas oculares sean simétricos; ahora, si aquella está entre el quiasma y el ojo, entonces forzosamente que las perturbaciones tienen que ser unilaterales.

Los trastornos del oído consisten en debilitamiento, rara vez sordera completa; hay casos en que, al contrario, hay una hiperacusia muy pronunciada. Suelen venir dolores muy fuertes en el oído, ó bien zumbidos ú otras molestias que pueden traer consigo el vértigo de Menière.

El olfato y el gusto generalmente se conservan íntegros, pues son raros los casos que se señalan de anosmia y más raros aún los de desaparición del sentido del gusto. Otro tanto pudiéramos decir con respecto á su exageración. Suele haber alfalgesia de Pitres en el mismo lado. La sensibilidad general sufre algunas modificaciones; unas veces hay anestesia principalmente en el lado paralizado; otras, al contrario, hay una verdadera hiperestesia de manera que el enfermo no soporta ni el contacto de la ropa; la sensibilidad al calor y la eléctrica sufren también trastornos muy variados.

*Motores.*—Las parálisis de los miembros son muy frecuentes, pero muy rara vez completas, contrario á lo que pasa en las hemorragias, embolias, etc. Muy á menudo ocupan los miembros de un solo lado comenzando por un grupo muscular, para irse estableciendo así lentamente en todo el miembro y pasar al otro del mismo lado; pero no es raro que ataquen á todos los miembros; en este caso, una hemiplegia simple precede á la parálisis del otro lado. Esto se presenta ó bien cuando hay multiplicidad de tumores, por ejemplo, ó bien cuando habiendo uno solo está situado de tal manera (sobre los dos pedúnculos, sobre las regiones medias del mesocéfalo) que produzca la compresión de los haces quinesódicos de todos los miembros. Es excepcional el hecho de una lesión localizada de modo que produzca una paraplegia. Los esfínteres generalmente conservan su libre funcionamiento. Estas parálisis unas veces son persistentes y otras no, sino que ó desaparecen enteramente ó se atenúan de tal manera que quedan simples paresias. La razón de esta diferencia estriba en la causa que las origina. Unas parálisis se producen por la compresión que directamente ejerce un neoplasma, y estas natural y necesariamente tienen que ser constantes, y hay otras producidas por trastorno circulatorio, congestión, edema y aún flegmasia, variables como variable es la causa que las motiva.

La pérdida del equilibrio es otro síntoma que se presenta, haciéndose notar sobre todo cuando el enfermo se levanta rápidamente ó haciéndolo marchar con los ojos cerrados.

La atetosis de Hammond se observa con bastante frecuencia, sobre todo en los casos en que es una paresia más que parálisis, ó que si existe esta no es constante y se ha observado que son los dedos por los que principia la convulsión en el ataque, los que ejecutan más esos movimientos vermiformes que caracterizan este síntoma.

Las contracturas de los músculos de los miembros se presentan aunque muy tardíamente, excepto en el caso de epilepsia Jacksoniana, de origen atrófico, pues en este caso son precoces y la Anatomía Patológica ha señalado degeneraciones secundarias de origen cortical en el pedúnculo, la protuberancia, el bulbo y el cordón medular antero-lateral. En estos casos existe la reacción de degeneración.

Las parálisis craneanas generalmente están del mismo lado de la lesión. En cuanto á la relación topográfica de estas y la de los miembros, es muy variable. Unas veces ocupan el mismo lado del cuerpo, otras son alternas ocupando lados contrarios, lo que sucede cuando el tumor obra sobre la porción periférica (células originales y cordón intracraneano) del nervio y no sobre su porción cerebral. En este caso y tomando como punto de partida los hemisferios cerebrales, el ojo está atacado después de su decusación, los haces motores de los miembros antes de su decusación y por consiguiente la parálisis debe residir por necesidad en dos puntos diferentes; del lado del tumor: para los nervios craneanos y del opuesto para los miembros. Si este es el caso, que más frecuentemente se observa, es por que los tumores generalmente están situados en la base ó regiones próximas, estando de esta manera en las mejores condiciones de ejercer una doble acción: directa sobre los nervios craneanos y cruzada sobre los de los miembros; por ejemplo, tumor que comprima el pedúnculo cerebral derecho, al nivel de la emergencia del motor ocular común; como este nervio no experimenta más decusación, y como los haces nerviosos de los miembros se entrecruzan antes de llegar á los pedúnculos, los contenidos en el derecho irán al lado izquierdo, de suerte que tendremos la parálisis alterna de Gubler que es un buen síntoma para el diagnóstico de los tumores de la base. Ahora supongamos un tumor situado en el hemisferio derecho, por encima de los cuerpos estriados y de los tálamos ópticos; la parálisis del ojo residirá á la izquierda como la de los miembros, porque los nervios del tercer par están ya decusados á este nivel de tal manera que la porción hemisfé-

rica del nervio del ojo izquierdo ocupa el lado derecho; de suerte que podemos reasumir diciendo que las compresiones de los nervios craneanos dan lugar á parálisis directas, si es en la porción periférica, y cruzadas si es en la porción central. Los reflejos generalmente se conservan ó están exagerados. En la mayor parte de las enfermas que hemos estudiado, los hemos encontrado exagerados principalmente en el lado parético. En una de las enfermas cuya observación va al final de este insignificante trabajo, al buscarle el reflejo rotuliano provocamos convulsiones clónicas que le empezaron por el pié, propagándosele á la pierna y luego al muslo hasta donde quedaron limitadas, y en otra, al estarle percutiendo los tendones de la cara anterior del puño, observamos que le vino un verdadero ataque de convulsiones generalizadas con pérdida de conocimiento, siendo mucho más enérgicas las del lado que percutimos, que era el que estaba más entorpecido en sus movimientos y atrofiado.

*Tróficos.*—Las perturbaciones vasomotrices son muy frecuentes; algunas veces sienten los enfermos un frío glacial en los miembros entorpecidos ó paralizados y á la simple vista se notan muy pálidos; otras por el contrario, estan excesivamente rójos y el enfermo experimenta una sensación de calor ardiente; pero no es esto todo, sino que hay una verdadera atrofia de los miembros del lado enfermo; en las medidas que hemos practicado hemos encontrado una diferencia de volumen de algunos centímetros entre los miembros correspondientes. La secreción sudoral unas veces disminuida y otras aumentada; igual cosa podemos decir con respecto á la sebacea; hay casos en que cae con mucha facilidad el vello de la piel. Las uñas á veces se adelgazan notablemente en el lado enfermo. Ya se comprende que á consecuencia de la parálisis de algunos músculos, predomina la acción de los contrarios; de aquí la diferencia de actitud que toma la mano por ejemplo, pero en ésta generalmente persiste la acción de los flexores; de aquí que cuando son constantes estas parálisis la articulación del puño experimenta una sub-luxación hacia la cara dorsal, hecho que hemos podido comprobar en algunos de los casos que estudiamos. Otro tanto dirémos del miembro inferior, de donde resulta que el pié toma una actitud muy distinta según los músculos afectados (piéd bot, varus, valgus, etc.) Por este hecho y por las paresias la claudicación es tan frecuente en estos enfermos.

El estado general es por lo común satisfactorio excepto cuando el vómito es tenáz y periódico, porque entonces se compromete la nutrición. Hay casos en que viene una gordura notable hasta la polisarcia. Con respecto al vómito tenemos que añadir que tiene todos los caracteres del vómito de origen cerebral; no hay náuseas ni perturbaciones gástricas; es sin esfuerzo alguno y falta la hipersecreción salivar que le precede generalmente cuando es de otro origen. La posición de la cabeza influye mucho sobre la aparición de este síntoma, de tal manera que basta muchas veces que el enfermo se coloque en el decúbito supino para que cese, reapareciendo cuando deja pronto esta actitud. Hay también descamaciones y gangrena superficiales, así como gangrena inminente vasomotriz, asfixia local de las extremidades de Reynaud.

Pasemos ahora á estudiar los síntomas del acceso própiamente dicho.

*1º. Aura.*—Puede ser sensitiva, motriz, y vaso-motriz. Muy frecuentemente el médico oye de los lábios del enfermo la descripción detallada y exacta de las sensaciones que experimenta antes del ataque, porque hasta estos momentos su inteligencia se conserva perfectamente. Del primer grupo, las de carácter anestésico y analgésico, son las que con más frecuencia se observan; es rara la hiperestesia; entre las vaso-motrices las sensaciones de frío ó de calor intensas, con acentuación del color de la piel ó palidez de la misma; el enfermo compara esto á la impresión que le causara si su mano fuese rápidamente sumergida en un baño helado ó hirviendo. Hay casos en que una abundante sudoración acompaña á estas sensaciones,

En cuanto á las motrices, ya es un temblor localizado en uno ó dos dedos; ya es la atetosis de Hammond, los dedos se doblan y se extienden alternativamente sin orden ninguno, exajerándose estos movimientos si el enfermo se obstina en dominárselos ó si fija mucho la atención en ellos; se les ha comparado á los movimientos que ejecuta un pulpo con sus palpas, ya es un solo dedo que se dobla y se extiende con movimientos rítmicos; ya se aplican los dedos de la mano unos contra otros de tal manera que á primera vista parecen sindáctilos; ya es el antebrazo que se dobla enérgicamente sobre el brazo, dirigiendo su cara interna hácia afuera; ya, como en una enferma cuya observación va al fin de este trabajo, se levanta todo el miembro como amenazante, ó ya en fin los ojos entran en nistagmus, fijándose hácia arriba y del lado paralítico, aunque sin estrabismo. Estas auras siempre tienen por caracter común el ser constantes; siempre se presentan con las mismas particularidades y el enfermo puede anunciar con matemática precisión el momento de su ataque. Su sitio y extensión están subordinados á los de la causa irritante.

2º. *Ataque.*—Según Rolland, en la mayor parte de los casos se encuentra una contractura inicial, seguida muy pronto de convulsiones clónicas más ó menos violentas, que quedan localizadas algunas veces al miembro en que principian, pero siendo mucho más común que se propaguen siguiendo un ciclo perfecto.

Efectivamente nuestras observaciones están enteramente de acuerdo con las ideas de Rolland, habiendo notado que cuando las convulsiones empiezan por el miembro superior, invaden en seguida la cara y después el inferior; si principian por el miembro inferior, ganan el superior y luego se extienden, y si empiezan por la cara, siguen el miembro superior y luego el inferior.

Los tipos más comunmente observados son el facial, el braquial, y el crural (este es el más raro).

Cuando habiendo empezado las convulsiones por un miembro se propagan, siempre predominan en intensidad las del miembro por donde empezaron. La duración del ataque es tanto menor cuanto más intensas y generalizadas son las convulsiones.

No es constante la pérdida del conocimiento. Durante las convulsiones la temperatura se conserva normal; el pulso y la respiración se aceleran.

En algunos enfermos la apatía intelectual se acentúa más después de los accesos. Uno de los enfermos que hemos observado se golpeaba fuertemente los carrillos después del acceso, y otro corría violentamente hasta agotar sus fuerzas. No todas las enfermas caen al suelo sino que, como el aura les da tiempo suficiente para acomodarse, hay muchas que se sientan para pasar su acceso en esta actitud. La duración media de este es de tres minutos.

#### TRATAMIENTO.

Cuando no se conocía la naturaleza de las lesiones, causa de la epilepsia Jacksoniana, se hacía uso para su tratamiento de los medios más variados, racionales unos, extravagantes otros, empíricos los más. Procuraremos exponer rápidamente los que más en boga han estado. Partiendo de una teoría falsa, antiguamente hacían abortar el acceso por medio de la ligadura enérgica del miembro por donde empezaban las convulsiones. De esta manera evitaban algunas veces que estas se generalizaran, pero una vez conseguido este objeto le quedaba al enfermo tal depresión, tal malestar, y tantos vértigos que muy pronto se oponía abiertamente á tal medio, prefiriendo las convulsiones francas.

Más tarde Bravais recomendó con entusiasmo la vesicación continua, de manera que se aplicaban al enfermo uno tras de otro, innumerables vesigatorios en todo el miembro que era el sitio de las primeras convulsiones. Este método fué muy detenidamente estudiado por Bentley y Todd, y últimamente, en 1861, por Brown-Séquard. Todos han convenido en que es incierto en sus resultados y

muy molesta su aplicación. Después estuvieron de moda las fuentes con cuentas de oro en el miembro enfermo, con idénticos resultados. Igual cosa pudiéramos decir de los sedales, moxas y cauterios que vinieron más tarde. También se recomendaban otras muchas sustancias al interior, como la belladona, el beleño, el óxido de zinc, el sulfato de cobre, el nitrato de plata, el cloruro de oro, el opio, el alcanfor y los bromuros; la hidroterapia, la electricidad, los imanes, etc.; pero en el estado actual de la ciencia pudiéramos sentar este principio general: "El tratamiento verdaderamente eficaz de la epilepsia Jacksoniana es la intervención quirúrgica." Con respecto á los accidentes sifilíticos, gomas cerebrales y otros, el tratamiento mixto está indicado; y aún cuando no se ha podido averiguar la naturaleza de la lesión, se debe hacer uso de este como piedra de toque. En el Congreso de Berlín de 1890, se expresó Horsley á este respecto de la siguiente manera: "Muchos clínicos admiten que el tratamiento mercurial y yodurado, resuelve siempre las gomas cerebrales y la paquimeningitis sifilítica. Ya Gowers, reconociendo que se obtiene con este tratamiento notable mejoría, ha protestado enérgicamente contra la opinión que acepta una regresión total. En cuanto á mí, estoy cierto que la paquimeningitis, cuya tendencia á reproducirse es tan grande aún después de la ablación, es únicamente mejorada y nunca curada por el tratamiento específico, y en cuanto á las gomas cerebrales debo decir, fundándome en la observación de varias autopsias, que muy poco debe esperarse de ese tratamiento, y que el único recurso para curarlas es la ablación por medio de la trepanación. Tengo éxitos. El mismo cirujano protesta contra la prolongación del tiempo en que se hace el tratamiento mixto como ensayo. "Opino que es muy sensible que no se marque un límite preciso á este ensayo, pues esta práctica nos obliga á operar algunas veces demasiado tarde. Según mi criterio el límite son seis semanas; si en este período no hay mejoría notable, no se debe vacilar y se debe practicar la trepanación exploradora." Como se ve, no se debe admitir en todos casos esta opinión absoluta en demasía de Horsley, y queda al buen tacto del clínico, y de la apreciación cuidadosa de los síntomas que presente el enfermo, seguir tal ó cual conducta.

Diremos pues, que los adelantos de la cirugía, debidos en gran parte á los trabajos interesantísimos de Demons, de Horsley, de Pitres, de Ferrier, de Championniér y de tantos otros, ayudados poderosamente en la ejecución por la práctica de la antisepsia, que hacen que la trepanación sea una operación cuya mortalidad es relativamente muy reducida, han contribuido á aliviar á estos desgraciados enfermos, condenados á llevar una vida miserable, que paulatinamente se extinguiría en medio de los atroces sufrimientos de los ataques epilépticos.

En México, las operaciones que se han hecho para curar á estos enfermos han dado felices resultados.

---

### EROTOPATHIA; MORBID EROTISM.

By C. H. HUGHES, M. D., of St. Louis, Mo.,

*President, and Professor of Neurology and Psychiatry, Barnes Medical College.*

Within the past few years the neurologist and the alienist have become familiar with so many strange morbid perversions and reversions of the erotic sentiments and sexual passion that they must be considered and classified in their relation to society, to morals, and to law. Science must severally classify these perversions of proper and natural human passion, as they may be found to be purely psychological moral perversities or to belong among the neuroses or the neuro-psychoses, and determine in them, respectively, the resistless or resistable involvement of the will. It must separate the psychoses of sexual aberration from the simple

neuroses of perverse sexual sensation and impulsion, without overwhelming impairment of volition, and these from simple moral vice, uninfluenced or unextenuated by neural disease. The sexually insane must be differentiated from such of these perverts as are not damaged in mind to the degree of insanity; a difficult task, yet one now imperatively demanded by psychiatry.

Westphal, Moll, Krafft-Ebing, and many others have presented instances of sexual perversion under the titles of "Urninge und Conträre Sexualempfindung," psychopathia-sexualis, homosexuality, etc., the *anima muliebris in corpore virili inclusa*, according to Ulrichs, himself a sexual pervert, and reasserted by Magnan, Kiernan, Gley, and Lydston.<sup>1</sup> Others have written upon frotteurs, sadists, necrophiliacs, anthropophagists (jack-the-rippers), sexual hermaphroditism, and other titles, all referring to the subject of perverted sexuality and morbid erotism.

Joseph Workman, of Toronto (American Journal of Insanity, Vol. xxvi, No. 1), in a paper read before the Association of Superintendents of American Hospitals for the Insane, June 6, 1879, has recognized among the insane, cases of the religious emotional type of insanity in whom exalted sexual feeling alternated with religious frenzy; and Schroeder Van der Kolk before this time called attention to the intimate relation discoverable between religious melancholia and an abnormal condition of the generative organs. We also have paranoiac, paretic, and lypemaniac forms and every possible intervening shade of mental aberration in morbid erotism, as well as simple erotic neuropathia without mental disease. This subject had not escaped the observation of Esquirol, who, describing erotic delirium, and referring to historic records, reminds us that the case of Heloise and Abelard presented an example of the association of erotomania with the prevailing religious sentiments of their time, and he thus draws the line between this morbid perversion of the passion of love and nymphomania and satyriasis. He also says:

Erotomania is to nymphomania and satyriasis what the ardent affections of the heart, when chaste and honorable, are in comparison with frightful libertinism; while proposals the most obscene and actions the most shameful and humiliating betray both nymphomania and satyriasis.

The records of lunatic asylums give us many examples of the delusion of sexual reversion and subsidiary delusions in harmony with this dominant morbid idea.

Dr. C. B. Burr, of Pontiac, Mich. (Medical Standard, August, 1893), reported to the American Medico-Psychological Association the case of a paranoiac female who imagined herself to be a man, and announced that her title was Lord George. She assumed the stride of a man in walking and the attitude of one while sitting. After six years' confinement the patient was relieved of a tumor, and now again recognizes the fact that she is a woman. Dr. Burr has noticed that of late years delusions as to change of sex are becoming more frequent. Marriages between females also occur of late more frequently; the "husband" usually being a criminal in male attire, who leads a double life; honest with the "wife," but criminal with a gang at a different time of the year. These latter, which are simply immoral cases, are to be differentiated from the pathological, though they may be both, thus complicating our subject.

Respecting the evolution of normal and natural love we may remark, as Thompson and Geddes have stated, that in most of the emotions and in the simpler intellectual processes there is common ground between animals and man. This is especially true of the emotions associated with sex and reproduction. The love of mates has its root in physical sexual attractions, but has been greatly enhanced by psychical sympathies. The means of sexual attraction rise from the crude and physical to the subtle and psychical with growth of love. The intellectual and emotional differences between the sexes are correlated with the deep constitutional differences, and are the natural divergences of normal variations in the

<sup>1</sup> Vide Psychopathia Sexualis.

organism. Male and female are complementary, and each in its own way. The love for offspring has grown as gradually as the love for mates. Even lactation and maternal care may be in part egoistic except in a few precociously tender animals. Genuine love for offspring is only emphatic in birds and mammals, where the reproductive sacrifice of the mother has also been greatly increased. The cuckoo illustrates the evolution of a criminal habit mainly due to constitutional conditions. Egoism and altruism have their roots in the primary or nutritive, and love in the reproductive activity. The divergent streams of emotion and activity have a common origin, subtly mingled at various turning points, and ought to blend more and more in one.<sup>1</sup> When we ascend from the lower animals up to man, and still further from the lowest human substratum of savage and semi-civilized man to the higher type of civilized and cultured manhood, we observe so refined and delicate a blending of passion and love that the two seem really separate and separable from each other, and in fact *are* so in the earlier and later years of human life, *i. e.*, before puberty and after the decline of virility in man or the passage of the climacteric in woman. Abelard, emasculated, jealously coerces Heloise into cloistered celibacy. These facts may have some bearing upon our subject. That function of love, jealousy, intimately allied in the lower animals and the lower order of man with the sexual life, has passed in process of the organic evolution of our species from an instinct of the lower organism to a place in the higher mind, regulated, restrained, influenced and influencing the sovereignty that resides in the intellectual centers of the cerebrum. Obeying the sovereign mind, its properly regulated indulgence gives health, vigor, and tranquillity; perverted by wrong volitions unrestrained, or by disease weakening the mind in its dominion, disquietude, diseases, disturbances, and tragedies follow. Morbid jealousy has helped to fill the world with woe. Its varieties<sup>2</sup> are: Jealousy of the senses (mere animal); moral or sentimental jealousy (heart jealousy); social or conjugal (which may or may not include the preceding).

Other facts of observation may aid us in solving problems of criminal responsibility in a class of cases germane to our subject, which we sometimes have to consider, viz, normal love. Normal love cherishes the loved one. Abnormal passion, solely selfish in desire and aspiration, considers not the welfare of its object so much as the wishes of self, but for the accomplishment of its end wounds body or mind and destroys both if necessary. Passion unrequited, vengefully breaks down all barriers. The mutual *odi et amo* of Catullus and Lesbia belong rather to lust than love. Love is tender, passion is violent. Love considers the loved one, passion regards only self and its instincts, impulses, and wishes.

We make no plea here in extenuation of genesic perversity, lust, rapine, pederasty, homoprostitution, etc. Disease does not ordinarily originate them. It only sometimes exceptionally excuses them. Salacity and sexual perversity may be solely immoral with no excuse in disease or pre-natal organic perversion. Sexual orgies the most revolting may coëxist with erotic disease on the part of some and without disease on the part of others who participate in them, as the London orgies of 1885, the Man-haters' dance in Berlin, and the floral festivals honoring the prostitute Flora of Ancient Rome, after Rome had, under the athlete and martial vigor of private and civic virtue, conquered the world and then had fallen a self-slain victim to her own unbridled luxury and lust. Normal love, too, has immoral perversities as abnormal love has its morbid perversions. Though there were Catos, who blushed at the shameless lasciviousness of these shocking floral games of the Roman arena played by nudity decorated with flowers, it must not be forgotten that the depraved populace of the amphitheater, neurotic and neuropathic alike, deliriously applauded this nude exhibition of men and women in lascivious attitude and public sexual commerce. Julius Cæsar was not, like his chaste wife,

<sup>1</sup> Evolution of Sex, p. 260.

above suspicion, for does not Suetonius, the historian, say of the conquerer of all the Gauls, that he was "*omnium mulierum virum et omnium virorum mulierem*"? Morals and civilization have advanced beyond those of Rome. There are now no amphitheaters and no temples dedicated to Isis, no Gardens of Priapus (at least no public ones). *Venus Voluptia* and *Venus Salacia* have fled from the public courts. Neither religion nor law nor the general morals now countenance the open rendezvous of the lecherous and debauched, and no Catullus sings in soiled Latin verse of lascivious perversion, though we still have the lascivious contortions of the *jardin mabile* and certain obscene forms of the modern ballet and certain modern love novels, suggestive, without the open consummations, of the festival of Flora.

We can not enter into the motives of a Tiberius, who, under the limitless license of the imperial prerogative, commits acts of monstrosity unfit for print, or of a Nero emasculating and publicly wedding a Sporus, but we understand Heliogabalus better. He loved the male slave who enslaved him and whom he made his wife and did not harm him. This was morbid erotism, and so appears the act of Nero above referred to; likewise the wedded union of Callistratus and Afer of Roman history. Certain we are that the lascivious libertinism and perverted sexual vices of antiquity, intermingled then, as now, in both neurotically sound and unsound organism, have not been obliterated from mankind. It has been passed along through the centuries. And we are confronted in this, as in all other studies of perverted functions of the nervous system and superimposed mind, with facts that belong alike to psychology and psychiatry, to neurology and neuroiatry, namely, atavic descent and direct hereditary transmission. To solve aright the problems of morbid erotism and psychopathia-sexualis we shall have often to go back in a given case, if not to ancient history, at any rate to the ancestral records of character, so far at least as the grandparents, as we have to do in rightly determining other questions in psychiatry.

The trend and purpose of this paper is to further emphasize the fact that there is a neuro-psychical instability of the organism dominating individuals to the extent of developing resistless aberrations of thought and conduct connected with the genesic sense, now attested by abundant clinical observation in the field of practical psychiatry, aberrations entitled to be classed among the insanities. The recent example of Alice Mitchell, the sexual pervert of Memphis, Tenn., who murdered her fiancée, Freda Ward, whom she so ardently loved that she wished to flee with her, marry her, maintain her, and live with her as a man would live with his wife, wearing a mustache and the clothing of a man, murdered her because she feared that Freda would be lost to her love, intending to cut her own throat at the same time, because without her life was no longer worth living, brings this and kindred subjects once more forcibly to the minds of alienists and recalls the records of history and of the writers we have just quoted.

It is not strange that in these days of overstrain and overindulgence of all the emotions, the propensities, and the passions of the mind inherent tendencies to neuropathic instability should display themselves, under the heightened pressure of favoring environment, in peculiar forms of failure of inhibition and in exaltation and perversion of the erotic feelings and the sexual powers, as well as in the other familiar forms of neuropathic involution with which neurology and alienism are now so familiar. There is as certainly a morbid erotism, or propensity to excessively and perversely indulge the love passion, as there is an alcoholism or alcoholic disease dependent upon an organic and inherited neuropathic or self-acquired instability. This instability is deeply laid in the molecular movement of the nerve centers which underlie the expression, emotion, impulse, thought, and action, by which the individual—the ego—acts upon feelings, suggestions, and inclinations originating within him in a manner different from what would have

been normal to him or natural to civilized mankind in general. And these feelings arise from external impressions which would not excite the same or similar emotions, thoughts, or deeds in those who are normally constituted. This is the true morbid erotism of the neuropathic, and it is, of course, a nervous disease of erotic instability. Neurology and alienism must grapple with it, place it, and classify it among the psychoses or the neuroses. The older writers have long ago recognized and described it in its aggravated forms as erotomania. Every now and then it forces itself on public and professional attention, as in the case just mentioned and other similar historic instances, and in its other forms, as in nymphomania, satyriasis, and in the manustupros that tenant our penal institutions and the homes of the imbeciles and the hospitals for the insane. Besides the well-known illusional and delusional forms of perverted sexual feeling, among females the modern Madonnas who bear anew the immaculate Christ and the modern masculine insane who, in transformed madness, imagine themselves the sinless sons of God, there are the sexual hypochondriacs among both male and female neuropaths and the opposite mental states of psychical and psychophysical neuropathic perversion. To the latter class belong many of the modern perambulating insane prophetesses of the Lord portending and proclaiming good or evil to the world according to the melancholic or paretic bias given to their distorted ideations by exalted or depressed cerebral activities; the under or over nourished state of morbidly acting ganglion cells in the cerebral cortex. Such, and many other varieties of perverted eroto-religious feeling and thought, are to be found in varying forms not here indicated both within and without the asylums. The paranoiacs are, as yet, mostly outside of these institutions. The public and the general profession, which knows little more of the delicate shades and intricate features of mental aberration than the people in general, have not yet sufficiently recognized it to secure the proper and timely sequestration of these pestilent cranks who are so pernicious to our personal weal and to the public welfare.

There are lypemaniacs and exalted erotics and those in whom shades of depression mingle with their exalted erotism and vice versa, and many intermediate grades of aberrant mental feeling, thought, and action. There are eroto-neuropaths and there are eroto-psycho-neuropaths, or more properly speaking, there are neuro-erotics who have reached the stage of sufficiently marked mental derangement to be classed as insane. There are many such. They are not markedly psycho-neuropathic in their erotism, but mainly unstably neuropathic. That is, though they have somewhat unstable nervous organisms in which a morbid erotism occupies and influences mind more than it ought, the mind in them has not yet become so weakened or disordered as that it sees not that the perverted erotic feeling is wrong, or sees not the propriety and necessity of resisting it. The mind does not succumb to, or become lost in, the morbid erotism. It is yet resistive, combative, and regulative. Still sanely balanced, though often assaulted by the morbid erotic feeling. The higher inhibitory centers of the supreme psychic area of the cerebrum still retain their physiological regulation and control. These erotics feel abnormally, but still act rightly. They yet belong to the domain of neurology, or neuriatry, if you will allow the coinage. Later, if their malady progresses, they may claim the attention of the alienist. They may pass into the domain of psychiatry. They are liable to become, at any time, under environment favoring the development of their disease, psychopathic, as well as neuropathic, and to need from without the restraint they can not exert from within upon themselves, over their erratic, perverse, and destructive erotic inclinations—the restraint and seclusion from the world which a properly organized asylum for the insane alone affords these unfortunates. The tendency of the age is to mitigate, if not to abolish, moral restraint. Freedom—physical, political, moral, mental—is the shibboleth of the people, and hordes of neuropaths, in whom impulses to moral degradation, entailed or acquired,

are unresisted, now come to the surface, that, in other ages, when laws were more rigid, were suppressed. The retrograde changes that have been going on in the morals of this country, as Esquirol said of France, "have produced more insanity than our political troubles." Neither did the revolution in France nor the rebellion in this country produce so much insanity as the sentiment of moral non-restraint or relaxation of self-control have done and are doing among those whose nervous organisms are inherently unstable. Sexual sensualism, to which those of neuropathic heredity are often congenitally predisposed, yielded to, brings on neuropathic excess and perversion of the genital instinct. When religion becomes simply a usage and a rite rather than a regulation of moral conduct; when the ambition of the age is to shine and scintillate rather than to grow in moral worth and in the grandness of self-control; when position and not self-equipoise is the purpose of the ambitious, and self-gratification of the pleasing propensities and passions and the indulgence of agreeable vices the aim of the many; when through pursuit of pleasure, without prudent restraints, unstable neurotics become still more unstable under the exhausting, irritating pressure of such adverse environment and pass from simple neuropaths, a little abnormal in their feelings, to fully-developed psycho-neuropaths, if love or the sexual passion be ascendant in the nature (and it is the dominant passion of mankind), the individual becomes startlingly deformed in mental feeling to the astonishment even of psychiatrists, accustomed as they are to seeing unique forms of diseased distortions of the mind. He or she develops into an erotic pervert or an erratic lover of his own sex—an "urning," a "*maedchen schmecker*," a sadist, fetichist, tribadist, etc.—an unnatural libidinous lover of a fellow-being organized like himself or herself, an erotopath (if you will accept this expression), and one of the momentous questions for psychiatry to now settle is when this morbid erotism, or erotopathy, is simply a neurosis, and when and where does it pass from simple neurosis into that degree of psychopathy which entitles it to be classified as insanity, uncontrollable, irresponsible insanity?

If we interrogate the records of this neurotic disease (*vide* Appendix, Workman's cases of alternating eroto-religious insanity and some cases from Krafft-Ebing), and from them endeavor to discover how much of grave psychosis and how much of simple neurosis we may find in them, we shall see by applying the accepted tests of alienism that the first five of Krafft-Ebing's cases epitomized in the Appendix show disease and perversion of sexual instinct, but they could not be classed as irresponsibly insane. The sixth case seems to have progressed to a mono-delusive stage as to her change of organism, with melancholia and suspicions of infidelity regarding the woman whom she loved.

We now invite your attention to the following, of which I have been personally cognizant:

A venerable and really good clergyman fell into disgrace from an act of exhibitionism, after the restraints of the higher intellectual centers over the lower and perverted instinctive impulses had weakened the once well-trained volitional powers of the reverend old man and caused him to go into retirement and professional obscurity. A lawyer of my acquaintance, of ability, but of lowly heritage he never cared to disclose, acknowledged to perverted homosexual instincts and impulses, and finally, under mortification and chagrin, and fear of disclosure of his perverted instincts, committed suicide. Cases like these are common.

In February of the past year (1892) a quiet, cultured, and gentlemanly appearing young man committed suicide by shooting himself at his room in a hotel in St. Louis. A combination of causes probably led to the despondency which ended in the rash act. Pecuniary embarrassment may have been one of them, but the chief cause, as elicited at the coroner's inquest, as testified by the male friend of whom he was enamored was that he had a morbid attachment for that friend. He wrote

long letters to him, teeming with endearing words. They had roomed together, but at the time of the tragedy they were rooming apart. This was his second attempt at suicide. At the time of his death he carried a locket about his neck containing the picture of the man he loved. He was an educated professional man, kind-hearted and of good address. The following letters, written in a neat hand shortly prior to and about the time of his death, serve to show the erotopathic condition of this young man's mind. They reveal the ardent feeling of the anxious, disappointed lover, much the same feeling as one madly in love might normally have for his heart's idol of the other sex, but never except unnaturally and abnormally for one's own sex, with homicidal and suicidal impulses of maddened desperation added:

MY DEAR FRIEND: Are you ill, angry, or merely careless? I looked for my usual Thursday's letter Saturday morning. It came not. I then felt sure you would write me on Sunday. I watched for the postman. No letter. He has been here this A. M., and still no letter. It makes me not only unhappy, but very anxious—unhappy since I am deprived of all that is left me to care for or look forward to; unhappy in the thought that I have displeased you; in suspense and anxiety lest some bodily ailment has seized that goodly frame and rendered you unable to communicate with me. If I do not hear from you in a day or so I shall be frantic and unfit for anything. I sent the stud on Thursday, which must have reached you Saturday, and not later than Monday, in which case I should have heard from you by this time.

MY DEAR FRIEND: I have just returned from the Cathedral, where Bishop Tuttle preached. My mind is not in a very receptive frame, so I can hardly tell anything he said. The pass was all a myth. The only pass I have is one into eternity. I even sold my dress suit and my old clothes to raise the funds to get here on. I came, intending to first kill you, then myself. I shall only make an end of my own miserable existence. My love for you has been my ruin. I can no more live a life apart from you than I can fly. The past month has been the test, and I can not do it. There is but one thing which could save me, and that is to pass the remainder of my life in your presence. I shall do that anyhow, for to die in your arms relieves death of half its terrors. I wish it would come to me naturally and you would have nothing to dishonor or grieve you. It is cruel in me to do this act, for it will blight your life. I should be more cruel to myself to try and live without you. You have done all but the one right and effective thing to save and make me, but it has all failed. I would gladly beg, steal, do anything—forego riches, forget friends, home, kindred, but for a life of blissful association with you. My office and outfit are all intact, and you can realize something on those things. Mr. C. H., X16 M. avenue, will see to the things. I appreciate all you did, and the effort and sacrifice you made for me. It was not in the right direction.

This letter to you is all I leave behind. I can not write anything to my parents. The blow will probably kill my mother. I shudder to think of it. We might have been happy together had it not been for W. The W., your brother's family, your other rich friends, your high social and business standing, your high ideas of morality, which you never filled—but 'tis too late; the end must come. I don't see why God did not let me die that Saturday night. I suppose there was some purpose waiting till you had made the outlay and sacrificed so much. You see, the end is all the same. Good-bye, dear I., I won't wish you happiness; you will never have that again and you will follow in my footsteps some time. Men of our natures and sins must have their punishment, and ours comes in a terrible shape. You are mine in the light of heaven, and no family ties can claim you from me in death. I pity you, but oh, to be free from all this agony of separation, suspense, doubt, is so welcome. May God deal with me according to my weakness. Keep my stud as long as you live; send my watch and ring to my mother. Let my last rites be attended by as little expense as possible. A pauper can not expect to repose in a metallic casket. I am going to bed, to sleep and gain nerve to face my fate. I have felt it must be, and since I have known you I knew you were to be the last straw. I have loved you better than you have ever been loved or will ever be loved again. Think kindly of that love sometimes. I am unworthy, but my love for you is worth a thought. Pray for my soul. Amen.

Much more than a sentiment of warm friendship for one's benefactor is breathed in these epistles of passion, desperation, and love, with its sequel of chagrin and suicide, without remorse for or full appreciation of the unnatural character of his

perverted love, though his Christian training had taught him to regard his unnatural passion as a sin.

The next record I have to make (from the proceedings of a recent public trial) is one in which this form of erotopathy developed into clearly defined insanity, with the murder of the loved object as its sequel. This girl was pronounced insane, on the witness stand, by Dr. John H. Callender, superintendent of the Nashville (Tenn.) Asylum; also by Dr. Michael Campbell, of the asylum at Knoxville, Tenn., and by Drs. F. L. Sim and B. F. Turner, of Memphis, and other physicians, including the family physician who attended the lady's mother through several attacks of puerperal insanity, at one of these confinements the lady under consideration having been born. Expert depositions sustaining the view of insanity in this case were taken of Dr. Charcot, Dr. Hammond, of Washington, and also that of the former family physician. The history of this case may serve to throw some light on the probable cause of the condition under consideration, for while there existed undoubted love and passion for one of her own sex, leading to jealousy, the victim of this form of sexual perversion was proven to have indulged in a very promiscuous kind of flirtation with the other sex as well, and the murdered girl, also infatuated with her murderer, was not always averse to the attention of men. How much may not mutual masturbation have had to do with the development of a morbid and perverse erotism in both? May not premature genital irritation, coupled with heredity, be a neurotic source of this baneful neuropathic perversion of the noble passion of love? Libidinousness, impurity, and lascivious sensuality are developed in this way, and by early bad companionship and salacious literature.

#### CASE OF ALICE MITCHELL AND INCIDENTALLY FREDA WARD.

Alice Mitchell and Freda Ward, two young women, loved each other, "not wisely, but too well." Their love culminated in a matrimonial engagement as between man and woman. The engagement ring was procured by Alice and placed on the finger of Freda. An elopement was mutually planned, and the clergyman to perform the ceremony was decided upon. Alice was to dress as a man, with a false mustache. "She knew she could marry Freda; she did not expect to have children," was her response to a physician's interrogatory (Dr. Turner's, after the murder) as to the impossibility of one woman marrying another, and "she could not be reasoned out of her idea that there was nothing preposterous in her marrying Freda." The elopement was prevented through intercepted letters and the vigilance of the relative with whom Alice was stopping on the very night it was to have taken place, while the steamer that was to have carried them away was at the landing (at Memphis, Tenn.). An enforced separation follows this discovery, some estrangement on the part of Freda, an attachment for a young man, which she later gives up and returns to Alice's love and embraces. They become again separated, have the usual lovers' misunderstanding, then jealousy succeeds on the part of Alice and its often sequel, vengeance. Alice goes in search of her recreant lover with her father's razor concealed about her person, finds her on the public roadside and remorselessly cuts her throat in the presence of the victim's sister and with her own sister in the buggy from which she leaps to do the murderous deed. She intended to kill herself, too, she says, but forgot it, because the murdered girl's sister belabored her with an umbrella. After the deed she went home, said she had cut Freda, and then began laughing and talking about other things. When the chief of police came to arrest her and asked how badly her victim was cut, she laughed and said, "Well, she bled mightily." She had had a whitlow and a thumb stall on her finger. At the time of the assault on Freda she had cut her own hand and blood was on the thumb stall. She put the thumb stall carefully away among her keepsakes, "because it contained the blood of both," she said. The next day, in a state of morbid mental exaltation, she read the account of her deed and of the death of her late beloved. She laughed over it and remarked upon it (so says the testimony) "as though she was not concerned in it."

And now we will let the unfortunate girl speak for herself as she testified, when summoned by the prosecution in the trial, the question being as to her mental condition. When placed on the witness stand in the court before which she was tried

as to her present mental status, this young lady deported herself and answered as follows to the questions of Attorney-General Peters:

Q. How long had you known Freda Ward (her victim)?—A. As long as I can remember.

The Attorney-General then asked about her visit to Golddust (a neighboring town) and she told in substance the facts of the tragedy. When asked if she met any young men at Golddust, she said she met two, Will. B. and Ashley R. Freda, she said, was engaged to R. Freda told her that Ashley had proposed to her (Freda) to run away and get married.

Q. Did you want her to marry Ashley?—A. No.

Q. Why not?—A. Because I wanted her myself. (Here witness broke down and wept briefly.)

Q. Did any words pass between you and Freda just before the killing?—A. No, sir; she only winked her right eye at me as she passed in front of the custom-house.

Q. Did that mean anything in particular?—A. Freda always told me that winking the right eye meant "I love you."

Q. Why did you follow Freda down the stone walk?—A. To cut her. (The girl's mouth shut down like a vise when she had spoken.)

Q. Why did you want to cut her?—A. Because I knew I couldn't have her, and I did not want anybody else to have her. I knew Harry Bilger loved Freda and I thought Ashley Roselle did, and I was afraid one of them would persuade her to marry him.

At first she intended to follow Freda down to the boat and kill her there, as it was a better place than the street. She could not explain why she determined to do the deed on the stone walk.

The witness, continuing, told her story of the killing, which coincided in every material point with the testimony of the preceding eyewitnesses. While everybody else in the court room, says the reporter of this trial, waited on her words with breathless interest, she settled herself comfortably in the chair and described the tragedy with infinite coolness.

As we carefully read this narrative and critically study all the facts, we discover the absence of ordinary motives which actuate the sane murderer. She gratifies neither malice nor revenge nor cupidity, in the ordinary sense of these terms, in the doing of the desperate deed. The natural womanly timidity in the face of such a crime, of one of her station and rearing, does not influence or deter her from its perpetration. She does not contemplate it with horror. Neither the self-interests of her heart, her pocket, or her passion are satisfied in the act. She does not gloat over it as one of just revenge, or lament it as one of unjust violence toward the one of all others nearest to her heart, as Freda Ward undoubtedly was. In her weak and insane mind she thinks it an adequate justification and thoroughly good reason for destroying the woman she so intensely and morbidly loved, that she "loved her and might lose her." This is the reasoning of love merged into madness. After the deed she confesses to no anger, makes no special plea in justification of it, admits no mistreatment, says she "would like to see Freda now," "she was beautiful and attractive," and she "loved her more than anybody else," and does not discern the incongruity of such an unnatural love, the impropriety of such a damaging admission, nor realize, as a sane person would on trial for her life, the horrible nature of the crime she is charged with committing. She had deluded herself into the belief that Freda, her heart's idol, was lost to her. This was enough. Fresh from a spell of despairing, insane grief, of love which imagined itself hurt, and with the very razor she had bought for the unnatural purpose of developing on her upper lip the manly attribute of a mustache, that she might in man's apparel pass for a man, she coolly cuts the throat of her affianced of her own sex without sign of regret. Now, let her speak on, and note the words and manner of insanity in her utterances.

As I started down the hill I took the razor out of my pocket, and when I overtook her I cut her with the razor. I slashed her throat with the first stroke. She pulled away a little and said, "Oh, Alice!" or something like that. Then came a scream from Jo Ward or Christina Parnell, I don't know which. I let go of Freda and turned around and Jo Ward smashed me with an umbrella, saying, "You dirty dog, what are you doing to my sister?" I said, "I am doing what I came here to do, and I don't care if I hang for it." Jo raised the umbrella to strike me again and I cut her on the chin, I think. I did not want to hurt Jo, but when she called me that name it made me mad and I did not know what I was doing. I had intended to cut Freda's throat and then cut my own, but Jo bothered me and so I ran after Freda and cut her again. I did not want to butcher her up that way. All I wanted to do was to kill her. Somehow, I forgot to kill myself.

Q. (By General Peters.) Were you mad at Freda for any reason?—A. No.

Q. Had she mistreated you?—A. No, she had not.

Q. What person did you love better than anybody else?—A. Freda Ward.

Q. Didn't you love your relatives?—A. Yes, but not as well as I loved Freda.

Q. Why did you write to young men?—A. Because I did not have Freda to write to any more (and here another gush of tears came, but were quickly dried as before).

Q. Would you like to see Freda now?—A. Of course I would.

Q. Would you cut her throat again?—A. I don't know what I'd do.

Q. Why did you love Freda Ward?—A. I don't know.

Q. Did you think she was beautiful and attractive?—A. I did.

Q. What were you doing in your room at home?—A. Crying, mostly.

Q. Where did you write those letters?—A. In my buggy.

Q. What were you crying about so much in your room?—A. Because I could not have Freda with me.

Q. You loved her like a sister, didn't you?—A. More than that (and once more the witness' voice shook and tears sprung to her eyes).

Q. Did you take laudanum once?—A. Yes, sir.

Q. Why?—A. Because Freda told me she was going to marry Ashley Roselle, and that she loved another girl besides me.

Q. Did you arrange to marry Freda?—A. Yes, sir; Dr. Patterson was to marry us. If he refused, some justice of the peace, or somebody else would do it.

Q. Did you not know it would not be right for one girl to marry another?—A. Yes, but I was going to dress like a man and I thought nobody would find out that I was a girl. I intended to take Freda to St. Louis and work for her.

Witness said she liked Jo Ward till Jo went on the stand and told stories about her; still she felt sorry for Jo since Freda was dead.

Q. Do you remember telling Freda in a letter that you would send a certain kind of rose to her?—A. Yes, sir.

Q. What kind of a rose did you mean?—A. I don't know now.

Then Gen. Wright took the witness in hand. To him she said she was to go under the name of Alvin J. Ward and Freda was to be Mrs. Alvin J. Ward.

Q. (By General Wright.) Were you going to have a mustache?—A. Yes, sir. Freda wanted me to have one. I didn't care for mustaches myself.

Q. How were you going to get one?—A. By shaving.

She said she first got the razor on the 1st of November last. Freda had told her that she and Jo would be down from Golddust some time in November. She had come near cutting Freda's throat on the 7th of January, when the latter passed her in front of a photographer's on Hernando street. "But Lillie Johnson was with me," said the witness, with something like a sigh, "and I could not get the razor without her seeing me. I did not want Lil to know what I was going to do."

Referring to her proposition to Freda Ward that they should both commit suicide by taking laudanum, witness said:

I told Freda when she refused that if she would go to sleep I wouldn't take the stuff; I didn't intend to take it, anyway. I intended to put the laudanum in her mouth while she was sleeping so she would swallow it when she awoke. She would not take it, so I concluded to take it myself.

Q. (By Major Fleece, a member of the jury.) Do you still want to kill yourself?—A. I have wanted to die ever since Freda did (said the witness sadly).

Q. Do you intend to try to kill yourself again?—A. I don't know, but I want to die.

Q. That thumb stall with the blood on it, do you want to preserve it as a keepsake?—A. Yes, sir.

Q. Do you think it will do you good to look at it?—A. Yes, sir; I'm sure it will.

During the examination of the defendant her father and brother watched her with ill-suppressed emotion. Tears coursed down the old man's cheeks, and when it was all over he was totally unstrung. Indeed, there was but one person in the large assemblage who did not feel the relaxation of the severe tension of that half hour, and that was the unfortunate prisoner herself. She was very cool. She seated herself so as not to crumple her dress and immediately entered into conversation with those around her, talking in an animated way and laughing at times in a gay manner entirely out of harmony with her surroundings.

The case was submitted without argument by both prosecution and defense, and within eight hours thereafter, the jury having retired, brought in a verdict of "Not guilty, by reason of insanity," and recommended her commitment to the State Asylum for the Insane at Bolivar, Tenn., where she now is.

It will be noted in the above case that this girl's insanity was decided not alone on the very apparent fact of sexual perversion, though she was not averse to the society of young men, but had recklessly flirted with a number of them at Gold-dust while visiting the Ward girls there (testimony of Mrs. Volkman), and admitted corresponding with them, but also and mainly on her often-proven insane improprieties, the evidences of insanity in the crime itself, and the general conduct and speech of the fair defendant herself, so evidently out of harmony with the natural character and surroundings of a sane woman reared and envired as was this unfortunate girl. The public estimate of this case may be gleaned from the following reportorial record made at the time in public prints:

If any doubt of her mental unbalance had lingered in the minds of the jury it must have been effectually dispelled by the manner and testimony of this witness. She ascended the stand with a steady step and seated herself carefully, arranging her drapery so as to set off her plump figure to advantage, and faced the arbiters of her fate with the unflinching unconsciousness of a child. She spoke in an easy, conversational tone, enunciating every word distinctly, and giving ready answers to questions put to her. There was not the slightest suggestion of bravado, but rather the frankness of one fully prepared and one perfectly willing to impart information of no special interest to the informant. She lost her serene self-possession only when speaking of the mutual love that had existed between Freda Ward and herself. At these passages she would cry a little, then brace up and go ahead as before. At first it seemed that the State had made no mistake in placing her on the stand, for she talked for awhile in a perfectly rational manner, but when she began describing the tragedy itself, and proceeded to tell how she cut and slashed her victim, and all without the slightest trace of emotion, every hearer felt that it was no sane being who spoke.

The jury at once saw the insanity of motive and deed. And so it must be with the psychological expert in making up his judgment in these cases. Sexual perversion is not necessarily insanity, though it may be and often is a part of it. It may be the beginning and may lead to it, and it may be and is often the end of it. It is a perversion of the natural feeling, of the sexual sense or instinct. It is neuropathic perversion, dependent on neurotic degeneracy, involving the brain, and the psychopathic instability of insanity may follow the morbid perversion of feeling, passing into delusive speech and conduct based upon it, disharmonizing the individual with his normal nature and surroundings. Then he or she is insane. The perverted feeling then becomes more than a mere morbid perception. It passes into a wrong conception of the mind, which is delusion. It biases and controls speech and conduct so that the individual no longer adapts himself or herself to the restraints and demands of propriety, or harmonizes with healthy nature or natural and proper environment. The victim is then insane. His perverted feelings and impulses dominate his mind and will. The perversion reaches the *ego*. The insane motive of this murder is apparent.

That sexual perversion is not necessarily mental disease may be proven not only by analysis of the numerous cases wherein the perverted feeling is accompanied with psychical resistance, shame and regret, but instances of the pervert practices

among whole tribes like those of the Pueblo Indians with their "mujerados," described by Hammond, and the "botes" and "burdachs" of the Montana and Washington Indians, as described by Dr. A. B. Holder, cited by Kiernan ("Responsibility in Sexual Perversion," in a paper before the Chicago Medical Society, March, 1892).

In the study of this subject mere perversities of the sexual act practiced from various rational but debased motives must not be confounded with organic perversity of impulse and conduct. The latter only is real disease; the other is only vice. The individuality of the person, the family and personal history, the violation of the proprieties, the existence of a diseased state of the brain and nervous system, the impulsion or deliberation, the motives and the question of disease are always to be studied in every question of perversity or perversion. A change of character may often be noted in true neuropathic perverts. Impulsions long fought against and resisted come finally to dominate the character, and the unfortunate individual becomes, like other insane persons, out of harmony with his surroundings and natural character, whereas the vicious pervert has learned his dirty tricks, has rational motives in their performance (filthy lucre often), and has ever been a willing victim. He neither loves nor dies for, nor kills, the object of his love. Depravity may make a business of vice and religion, as in the Temples of Venus and the Gardens of Phallus.

Hammond's description of the Zuni "mujerado" and the practices connected with this sexual pervert may be properly placed here:<sup>1</sup>

The Pueblo Indians are in the habit of selecting some one male from among those living in a village and rendering him sexually impotent, reserving him at the same time for pederastic purposes. This person is called a *mujerado*, a corruption probably of the Spanish word *mujeriego*, which signifies feminine or womanish. There is no such word in Spanish as *mujerado*; but if there were, it would, according to the construction of the language, mean "womaned," or "made like a woman." A *mujerado* is an essential person in the saturnalia or orgies in which these Indians, like the ancient Greeks, Egyptians, and other nations, indulge. He is the chief passive agent in the pederastic ceremonies, which form so important a part in the performance. \* \* \* For the making of the *mujerado* one of the most virile men is selected, and the act of masturbation is performed upon him many times every day; at the same time he is made to ride almost continuously on horseback. From overexcitement comes abolition of the orgasm, the organs atrophy, the temperature changes, and he becomes assimilated with the female sex, perhaps at first with reluctance, but finally with entire complaisance and assent.

Sanity in a savage may be lunacy in a civilized being.

On this and kindred practices Kiernan remarks:

The influence of old religious practices long persists after the basis of these has disappeared. Such practices reappear at the seats of old Greco-Roman and Greek colonies in France, Germany, Italy, and elsewhere. The Zuni "mujerado" is hence not the evidence of either immorality or insanity it would be in an Anglo-Saxon race.

The Scythian *Enares* of Herodotus or the *anandrii* of Hippocrates, whose condition was so well explained by the skeptic Father of Physic, were sexual perverts whose impotency was caused by similar natural cause to that which weakened and destroyed the power of their legs. They were sexually weak and womanly, not from the retributive vengeance of Venus, whose temple they had pillaged at Ascalon, but from the long and unremitting marches in the saddle with their legs unstirruped. According to Hippocrates these Scythians wore breeches and passed the quarter part of their time on horseback with their limbs hanging without support, and "the disease attacked the rich and not the lower classes." The noble and powerful were its chief victims, "because they go much on horseback, while the poor do not." "These infirmities are widespread among the Scythians, who

<sup>1</sup> Journal of Nervous and Mental Diseases, 1882.

are not the most impotent of men." Hippocrates himself, however, drew a wrong conclusion respecting the influence of the cutting of the veins behind the ear in causing this sexual impotency.

The changes in character that take place in these perverts are the physiological results of lost virility, and the lost virility results from natural causes. The orgies and tribal rites associated with these sexual perverts were in some instances the result of delusive misconceptions as to the significance of the fact, but not the insane delusion of disease either on the part of the individual or tribe. The same is probably the true *raison d'être* for the conduct of the nomadic Nogays or Mongutays of Caucasus who, as they become old or sick, lose their beard and their sexual feeling, don the dress of women, and thereafter live apart from their own sex and in the society of women exclusively.

We have given the public opinion on the subject of Alice Mitchell's mental condition. The following summary by Dr. A. B. Holder, of Memphis, Tenn., gives the points on which the medical experts based their opinion that this erotic or sexual pervert was insane:<sup>1</sup> (1) Puerperal insanity of the mother before and at the birth of Alice (she was several months in an asylum) and insanity of uncles. (2) Her boyish tendencies in girlhood, indifference to young men's company, and general peculiarities, headache, etc.; her lack of mental development, seeming five years younger than her true age. (3) Her intense and peculiar affection for Freda Ward and her earnestness in the irrational idea that she could marry Freda. (4) Her murder of Freda, its cause, and manner. (5) Her words and manner when speaking of Freda and of the murder. These points are all presented in the history we have given of this remarkable case.

Per contra, we give an editorial extract from the New York Medical Record, in which the distinguished editor boldly cuts the Gordian neurotic knot, which alienists have so long been seeking to untie, with a temerity that settles the subject for him, perhaps, but not for the writer of this paper. It is a judicial finding, not an editorial fiat, that we now want. It is to unravel, not simply to summarily cut through with the scalpel of medical editorial dictum that this inquiry into these singular cases is made. All are peculiar! Some are insane! We would know who among the number, and when they are insane, and who simply are peculiar, yet responsible. To the alienist the question, as in moral insanity and other forms of affective mental aberration of differentiation of disease and depravity, often causes profound hesitation and sends him in search of the true data of alienism for sometimes even an uncertain decision. Dr. Shrady says:<sup>2</sup>

The young woman was afflicted with an affection which Science, with a big S, calls psychopathia sexualis, and pronounces the subject a victim of a perverted sexual instinct. The pervert in this case attached herself to a Sapphic friend, whom she killed one day in a fit of jealous fury. On trial, the defense of insanity was made. The medical experts were, we believe, unanimous in pronouncing the case one of a primary degenerative insanity, and the jury brought in a verdict of insanity.

We do not wish to contradict the combined testimony of so many alienists with reputations evidently very high in Memphis. Technically, perhaps, the girl was best considered insane; but we can not avoid believing that if this alleged lunatic had been treated for worms, leucorrhea, constipation, or some other of the frequent mechanical excitants of unhealthy sexual desire, or if she had been taken in hand early by those in authority and received a course of bread and water and, perhaps, some strong corporeal applications, she would not have become a Lesbian lover or a murderess. (Possibly, but this girl did become so and she was insane.)

There is no function easier to control or to corrupt than the sexual. While some sexual perverts are born so, the majority are not, but form their habits through gradual vicious indulgence. Nearly all are amenable to moral influences; that is to say, to rewards and punishments. The sexual pervert may be

<sup>1</sup> *Vide* Medical Fortnightly, August 15, 1892.

<sup>2</sup> New York Medical Record, August 13, 1892.

technically insane, but he or she is legally responsible, and should be so held. (Not if the motive of murder proves, as in this case, the insanity of the deed.)

Alienism does not say that all psychopathia sexualis is insanity. It modestly and cautiously inquires how much of insanity there may be in any given case of sexual aberration, and in determining the question applies the datum of alienism—the rule of departure from natural thought, feeling, or action, based upon disease perverting the brain and mind.

In Kiernan's contribution to our subject, to which we have already referred, another homicide resulting from this perverted passion is cited in the person of Miss D., a young lady of masculine taste, who, in 1878, "loved another young lady of Pocomoke City, Md. An attempt was made to break off the relationship, and an engagement was entered into with a young man, whereupon Miss D. shot her lover dead. She was tried and found guilty of 'manslaughter in heat of passion.'"

Parent-Duchatelet, in his work on Prostitution, gives at least one example of female love, jealousy, and bloody violence toward another female, somewhat like the case just cited, and Krausshold records the instance of another violent Lesbian lover whose passion passed into the insane delusion of being with child by the woman she loved, while Mantagazza gives several instances of actual marriage as man and wife between women.

Scattered through the literature, especially through that of legal medicine, and psychiatry are to be found instances of the most singular forms of this insanity of passion, but the true psychology of love and lust and the psycho-pathology and psychiatry of the sexual passion have yet to be written. Many inexplicable features of erotic perversion and psychopathia sexualis remain to the student of mental and moral science.

As we are about to conclude this paper, a case which may yet prove another *cas célèbre* is recorded in the public prints:

Two girls are arrested in the streets of a Western city (Indianapolis, June 27), whose erotopathia simulates that of Alice Mitchell and Freda Ward, without, thus far, the tragic ending of the latter. Their names are given as Delia Perkins and Ida Preston. They had run away from home together because of their love for each other. Delia had cut off her hair and offered it for sale in order that she might obtain money on which to help defray the joint expenses of herself and the loved Ida. When Delia's stepfather was summoned by the chief of police to come for his runaway daughter, she threatened to kill him, and when he came treated him coldly. To her stepfather's importunities to go back home with him she only finally agreed on promise of being permitted to see Ida whenever she should desire to, imprinting burning kisses upon the cheeks and lips of the paramour of her own sex on parting. These two devoted girls had been together almost constantly since their departure from home and they had not been in the company of gentlemen. The intense and active passion seemed to be on the part of Delia, Ida being reported as regarding the matter "as a huge joke." When Delia was returned home the following colloquy took place with her mother (now Mrs. Mendenhall):

MOTHER. You will not run away again, will you?

DELIA. Not if you let me go with Ida.

MOTHER. That I will not do.

DELIA. Then I will kill myself and you will be responsible.

MOTHER. Don't say that. We will try to make you happy and you must try to forget all about Ida. I can't understand why you do not forget this foolish fancy and fall in love with a man and marry him.

DELIA. I do not care for the best man that ever walked, and never will. Ida is the only one I ever loved and I will continue to love her until I die, and if we are not allowed to go together *I will kill myself and her, too.*

Miss Perkins told the reporter that she had not left home because she had been mistreated, but because of her love for Ida Preston. "My parents refused to let me go with Ida," said she, "and I decided to be with Ida, let the consequences be what they might."

Miss Preston stated that she had been met in the street by Miss Perkins; that the latter said she was tired of staying at home and said she was going to leave. "I didn't want to leave home," said Miss Preston, "but Delia told me she loved

me so dearly that if I did not consent to go with her she would kill herself and me, too. I like the girl, but don't believe I care as much for her as she does for me."

It is obvious that the limits of an essay forbid us to introduce the many special forms of sexual vice or disease or to engage in specific discussion. A diligent search for cases in the writings of Moreau, Tardien, Marc, Caspar, Cullerre, Coffignon, Tarnowsky, and others mentioned in the text and Appendix, would suffice to show how futile any such attempt would be. However, as we are only here concerned in finding the correct principle of mensuration and analysis for these singular psychical freaks, a mere reference to a few typical cases suffices our purpose. A feature of most of the undoubtedly insane is the threat to kill the loved one or attempted murder, and threatened or attempted suicide. Having thus as delicately dealt with this indelicate subject as its nature would permit, a subject which the perversity of neuropathic organism has projected upon the field of scientific adjudication, I offer for your distinguished consideration the following propositions as legitimate conclusions from the facts set forth in this paper and in all other literature germane to our subject, in conclusion, we think the following are sustained or are sustainable from the present or more extensive study of this subject:

(1) Morbid erotism presents both normal and abnormal psychological aspects. It therefore presents a voluntary deviation from the ordinary and natural indulgence of the genesic instinct—the normal, but immoral psychology of the eroto-sexual propensity, and instinctive, inherent, organic, dominant, and often resistless involuntary perversions of this passion, the latter being the true abnormal and organically unnatural sexual perversion, the reverse, or contrary sexual instinct. This is the psychiatric aspect of the subject, the one that most concerns us as alienists and neurologists.

(2) Love and the genesic sense are not one, as is shown in the antedating of love to the appearance of the sexual feeling, in the developmental period up to puberty and its survival beyond the menstrual climacteric in women. In the organic evolution of the individual, love antedates the birth and survives the decay of the sexual feeling, though it is intensified or diminished or otherwise modified or influenced by sexual states.

(3) The duty of the hour is to search out the complicating neurological and neuropathic factors, and the predetermining neuropathic conditions, the neurology and neuriatry, immediate and ancestral, of these unique morbid and unnatural eroto-genesic perversions; to weigh in conjunction the potentialities of physical or psychical environment, and determine as satisfactorily as we may, in the light of clinical and historic facts and physiological and pathological states, the true mental status of the eroto-sexual pervert with regard to:

(a) Responsibility to law with reference to specific perversions and ordinary crimes growing out of the eroto-genesic passion.

(b) Social status of sexual perverts.

(c) Substitutive acts, manustupration, body contact, incest, bestiality, etc., are not always to be classed as morbid perversions, but as purely immoral acts.

(d) In every inquiry the line should be drawn between morbid erotism, which is either an eroto-genesic perversion of pure Platonic love without genesiac concomitants and perverted lusts, or pure organic unrestrained, unregulated licentiousness, dissociated from love, or in which love is abeyant or insignificant and secondary.

(e) The conclusion of the matter is, that we are confronted in the study of this subject with conditions which are morbid, organically neuropathic and beyond the governing influence of volition, and, *per contra*, with other conditions which, while they may in a certain sense be organic impulses, are yet within the range of normal volitional control.

To the latter class ordinarily belong rape, incest, bestiality, and other unnatural crimes, the so-called "fetiches and manustuprates," while to the former belong the true morbid erotics, the urnings, the masochists, sadists, etc.

Medical science must study to determine for society and for the state what is restrainable and vicious, and what are the morbid and resistless organic impulses of these *bizarre* eroto-sexual states, viz. : the true sexual insanities or psychoneuropathic perversions.

(4) This inquiry involves a study of hystero-erotic attachments and aversions, erotic trances, ecstasies, beatitudes, divine amours, immaculate conceptions, etc., as well as the true *conträre sexual empfindung* or psychopathia sexualis. It involves also certain morbid erotic perversions sometimes observed in epileptically insane females, such as vaginal mutilation with glass, pins, and needles inter vaginum, etc., epileptic and neurasthenic exhibitions, etc., during a psychical equivalent. We include all under erotopathia.

In every study of morbid erotism the distinction between love and lust should be sharply drawn, as between healthy erotism and perverted or debased sexual passion. This is necessary to a proper understanding of those historical and everyday recorded instances of pure but perverted Platonic affection and those oft-recurring and startling reversions of sexual love into murderous hate and passion, so often chronicled in the public press. The excesses of Heliogabulus and Hierocles, the Lesbian love, the *odi et amo* of Catullus, the Grecian youth defiling the statute of cupid in the temple of Delphi, and those horrible Artusian *libidos* of later date, whose morbid *vita sexualis* feeds, like the tiger's rage, on blood, require of us critical psychological analysis. These are to be compared and differentiated from the unrestrained but restrainable excesses of satyriacs and courtesans. There are Theodoras and male satyrs in human form in our day, as in the days of ancient Rome, whose excesses can not be extenuated on the charitable plea of disease. While science should cast the mantle of charity over morbid impulses yielded to in resistless psychopathic states, it must draw the line between similar impulses (depraved and but slightly, if at all, morbid) cultivated and gratified in normal psychical conditions. It must separate disease from depravity of mind, and herein lies the difficulty of our subject. The question of crime and insanity, often difficult to solve, devolves upon us as medico-jurists to determine from known and yet to be acquired psychologic and psychiatric data. The subject is primarily neither one of sentiment nor morals exclusively, but mainly one of psychiatry, to the study of which the data of alienism and psychology should be rigidly applied in all questions of medical, moral, and forensic inquiry.

Finally and fortunately, something, and in some instances much, may be done for these victims of *libido morbosus* by treatment. Sexual and psychical erotism may be subdued, the mind and feelings turned back into normal channels, the homo and hetero sexual changed into beings of natural erotic inclination, with normal impulses and regulated restraint, by a suitable hygiene and therapy; medical, hypnotic, and in some cases surgical remedial treatment is hopeful of curative results in acquired sexual perversion, but only of repressive results in hereditary sexual perverts. Society, organized into government for the better security of person and property and personal and collective happiness, is specially concerned in the maintenance of chastity and morals. Personal and collective happiness depend upon this. The state, therefore, as Krafft-Ebing insists, can not be too careful as a protector of morality in the struggle against immorality; for sexual crimes are on the increase in our modern civilization, as shown by the statistics of Lombroso and Caspar, to which Krafft-Ebing refers, and by the startling records of the public press. Considerations of psychical sanitation demand alert attention to this subject from physicist, moralist, and jurist. The moral pestilence

is in our midst. Sodom and Gomorrah are revived and surpassed. Law, ignoring psychiatry and dealing violently with some flagrant forms of sexual vice, punishes the criminal as a wholly responsible being (but temporarily), and allows him to return and pollute society; whereas psychiatric science, knowing how deeply laid these sexual perversions may be in degenerate nerve element, which law can not correct, asks for their victim's perpetual sequestration from society and a radical asexualizing surgical procedure, such as the father of Heloise visited on Abelard. Inspired only by the spirit of vengeance, law protects society by punishing the criminal, while medicine would mercifully protect both society and the maimed victim of a sexually and mentally degenerate organism, whose acts are often as resistless as the mandates of a tyrant, because they spring from the despotically perverted cell life of a nervous system as badly endowed by pathological heritage as that of the average epileptic, and whose life is often equally as explosive. Nevertheless, as Krafft-Ebing truly states, the nature of these acts can never in themselves determine a decision as to whether they lie within the limits of mental pathology or mental physiology, and while most of these cases, to the honor of our humanity, fall within the scope of disease, we must here state again, in the language of the author just quoted, that "it devolves on psychiatry to show in any given case before the law that the perverse expression of the sexual feeling is founded in a pathological condition of the organism."

---

#### APPENDIX.

While it has not been deemed necessary for our purpose to go into further detail of the varieties of sexual perversion, some of them being disgusting even to the cold vision of the scientific student of psychic perversion, yet the physician and the jurist can not ignore them any more than they can refuse to become familiar with the clinical features of foul disease or the details of revolting crime. Following are Workman's cases:

*Case I.*—A small and handsome woman, aged 39, of delicate structure, the mother of four children, was admitted into the asylum in 1860. Her insanity was of a very fervid religious type. She had escaped from home and was found after considerable search, with her younger child, in the church to which she belonged. She manifested well-marked hysterical aberration. I found her always too desirous of prolonging conversation and I took care to preserve a duly cool demeanor toward her. In four and a half months she had apparently regained mental integrity and was taken home by her husband. She continued well for nearly two years, when her insanity recurred in a very aggravated form. She evinced very warm, and I believe sincere, religious feeling. She was a constant and devout reader of the Scriptures and of select religious books, and so long as she continued able to attend she never missed divine service. The same tendency to prolonged and rather close conversation was again presented; she was the subject of intense hysteric seizures, in which the somatic movements clearly indicated that the uterine system was deeply implicated. At the end of four years this poor woman was released from her infirmities. The post-mortem examination gave revelations of serious morbid changes in the chest, abdomen, and pelvis, while the brain was found unaffected. The lungs contained numerous cheesy nodules, and showed old, firm costal adhesions. The abdomen contained about a gallon of greenish fluid. The peritoneum was thickened and coated with a green, cheesy deposit. The intestines were similarly coated and were glued together in an inextricable mass. Both ovaries were much enlarged and were transformed into cheesy matter. The uterus was covered with the general cheesy coating and its texture was much changed.

It might be difficult to decide in what part diseased action had had its commencement in this case. The uterus and ovaries may have been the primary seat or they may have been but simultaneous sharers in the general deterioration; but from their abnormal condition we may regard the salient manifestations of the insanity as having sprung. I was informed by her former medical attendant that he had found the erotic-tendency a serious difficulty to deal with.

*Case II.*—Sometime previous to the preceding case another, of similar but more aggravated character came under my care. The patient was 44 years old and had borne eleven children. She was spoken of by her religious pastor in the highest terms of commendation. Her medical attendant designated her malady as nymphomania, and it may suffice for me to say here that the manifestations justified the designation. This woman's religious sentiment, notwithstanding her indomitable sexual tendency, was not obliterated. It was indeed painful to witness the incongruous coincidence. She died three years and a quarter after her admission.

The most remarkable facts exhibited by the post-mortem were the following: Hépatization to some extent of both lungs and numerous pleuritic adhesions. Several tubercles beneath the peritoneal coat of the ileum. An unusual fullness and rotundity were observed at the promontory of the sacrum. On removing the vessels and cellular tissue the enlargement was found to extend upward along the sides of the fifth, fourth, and third lumbar vertebræ. Fluctuation was quite perceptible. On opening the dilated membranes a quantity of creamy pus flowed out. The inter-vertebral cartilages appeared completely dissolved away and the bony structure was so softened that the scalpel easily penetrated it. The uterus was retroverted so fixedly, that when forced into the normal position it instantly, on being let go, retook its retroverted state.

*Case III.*—An interesting and pious young lady was very assiduously, if not skillfully, treated by her medical attendant, who had the misfortune to be very attractive. He diagnosed, perhaps correctly, uterine trouble, and being a specialist in that line of practice, he adopted the treatment which he considered indicated. It had, however, been necessary in order to arrive at exact knowledge of the state of the affected organ that a certain process of examination, not very compatible with virgin delicacy, should be instituted, and a repetition of this process was called for at each appliance of the topical remedy employed. All this must or should have been very irksome to the physician and very distressing to the patient, but custom reconciles us to many inconveniences. Had he better understood the peculiar susceptibility of women of fine-toned nervous temperament and religious emotionality, suffering under uterine disturbance, he would have made his visits as short and unfrequent as at all possible. Instead of so doing, he came often and remained long, cheering his patient with lively and kind conversation. She had religious anxieties, and doubtless he assumed the supplementary function of spiritual comforter. The actual state of affairs was, she was drifting into insanity, and he did not soon enough make the discovery. She had, despite the topical annoyances, fallen grievously in love with him and a severance had to take place. I was subsequently consulted. There was no doubt of her insanity, but her friends ascribed the malady to disappointed affection, and the unlucky uterine specialist now rests under their strong displeasure. I have since seen a case in which, from similar inadvertency, the same gentleman, in the management of a religious young lady, got into a similar predicament, but without the interposition of specular manipulation. A few more mistakes may bring him light.

*Case IV.*—The next case was that of a preacher, who, at the time of the development of his insanity, was very actively engaged in the work of a revival. He was newly married, and had for several weeks preached, in different places, three times daily.

He was brought to the asylum in a state of utter frenzy, and continued so for three weeks. The fact of sexual excitation was too patent to be overlooked, and it required not the information given me by his friends to satisfy me of the association which had subsisted between his religious fervor and excessive sexual indulgence. He made a good recovery and became a moderate man.

Complements of these cases in the females are doubtless well known to our gynecologic friends, and doubtless too well and too painfully so to some of the younger and less cautious and experienced wielders of the speculum. But gynecology, like psychiatry, lives and learns.

The following cases, abstracted from an article on "Perversion of the Sexual Instinct" (Report of Cases, by Prof. von Krafft-Ebing, which appears in the *Alienist and Neurologist*, Vol. IX, No. 4), will serve as sample records. His book, *Psychopathia Sexualis*, which has since been well translated by Dr. Chaddock, of St. Louis, has a far greater number and in far greater variety:

*Case I.*—Mr. X., merchant, 38 years old; residing at the time in America; disposition feminine; fond of music and literature; hates noise, disturbance, and obscenity. As a child he associated constantly with girls and played with dolls and toy

kitchens. Liked to dress in girl's clothing; when a student took no part in the gymnasium; delighted to help his mother with her household duties. At the age of 13 acquired a fondness for one of his own sex. At school he always had a lover and was horribly jealous of any girl or schoolmate toward whom his lover showed any preference. His delight was to kiss him. Had desire toward him, but propriety overcame it. Until he was 28 years of age was free from onanism, pederasty, or involuntary emissions. While still a young man he had a serious love affair with a sophomore, who returned his love with the enthusiastic friendship of a boy only, would kiss him and have erections with him. He raved over poetry and literature, and grieved when forced to be absent from him. The young ladies of the house where he lived had no such effect on him. He associated with them only in a friendly but entirely dispassionate manner.

Other Platonic love affairs with young men followed, but he realized his unnatural condition and was depressed over the knowledge of it. He never found in the society of beautiful women that invigoration of the mental powers which is commonly the case, but did find it among fascinating young men. He preferred to associate with married women or entirely innocent and disingenuous young ladies. Every attempt to draw him into the matrimonial net disgusted him. He sought the companionship of others like himself. One evening in the castle garden at X., where those constituted like himself were accustomed to seek and find each other, he met a man who powerfully excited his sexual feelings. \* \* \* He would go often to the park and sought similar places in other cities. He formed an acquaintance with a young man who was eccentric, romantic, frivolous, and without means, who obtained complete control over him and held him as if he were his legal wife. He was obliged to take him into business. Scenes of jealousy followed. Repeated attempts at suicide were made by this new acquaintance. He suffered terribly by reason of the jealousy, tyranny, obstinacy, and brutality of his new acquaintance. When jealous he would be beaten and threatened with betrayal of his secret to the authorities. After this new-made lover had cost him 10,000 francs and a new attempt at extortion had failed, he was denounced to the police, arrested, and charged with having sexual relations with his accuser, who was equally guilty, and condemned to imprisonment. This destroyed his social position, brought his family to sorrow and shame, and the friends who had heretofore held him in high esteem now abandoned him with horror and disgust. \* \* \* The manner of satisfying his sexual desires was not buggery, but a sort of onanism, produced by handling the genitals of another, whereby a healthy but not extremely exciting flow of semen would take place, after which he would feel refreshed and relieved. A bright, fun-loving young lady, who, as a woman, made no erotic impression on him, dressed herself in the uniform of an officer, with mustache, etc., and thus excited a sexual passion toward herself. A friend once advised him to marry and dress his wife in male attire. This pervert knew of a case in Geneva where an admirable attachment between two men like himself had existed for seven years. X. confesses that their "loves bear as fair and noble flowers, incite to as praiseworthy efforts as does the love of any man for the woman of his affections. There are the same sacrifices, the same joy in abnegation, even to the laying down of life, the same pain, the same sorrow and happiness as with men of ordinary natures." X. is described as of perfect physical build, with nothing remarkable as regards his sexual organs. His walk and voice are masculine.

*Case II.*—Count Y., 34 years of age, German, bachelor, consulted with Krafft-Ebing, in 1882, for nervous debility and abnormal sexual impulses. He was of muscular, masculine appearance, and, "with the exception of neuropathic eyes," was in no way outwardly remarkable. His mother was a woman of a highly organized, nervous, passionate nature, whose mother was extremely eccentric. His father was somewhat mentally deficient. Two sisters are apparently of normal intellectual qualities and of an entirely normal physical organization. The patient appears as an average man, somewhat overstrung, poetically inclined, and of fine feeling. As far back as he can remember he has had erections and sexual desires. In childhood he was attracted as much toward boys as girls, but toward the latter in an entirely Platonic manner, while toward the former he was sensually excited. He played soldier and preferred the company of boys. In his youth his sexual desires tended still more toward males, and he preferred to dance with boys. At 21 years of age the itching of a flea bite led to masturbation, which he practiced for several years and became highly nervous in consequence, but later abandoned the vice. At 22 he made an attempt at copulation, which disgusted him. He made no further attempts. A woman's breast seemed to him lacking in symmetry, and reminded him of the udder of a cow. Masturbation performed on him, however, by a woman aroused lively erections and sensual gratification. Afterwards his perverse sexual desires toward the other sex took a new turn, through voluptuous

dreams in which the woman would beat him, and thus excite sexual desires. He hired a courtesan toward whom he felt no æsthetic or intellectual interest, who must stamp on him with her feet and strike him with a whip to arouse his passions to the highest degree. Then he would lick the woman's foot. The foot of a woman or of a boy is the only thing that sexually excited him. With that his sexual excitement would reach its height, and an emission would take place, followed by a sense of degradation, sexual satisfaction, and disgust. His genuine sexual feeling, however, attracts him to those of his own sex. This patient does not feel unhappy in his perverted sexual instincts, but deplores the fact that social customs deny him the highest sexual enjoyment. His practices with women are but unsatisfactory makeshifts. His erotic dreams are of intercourse with boys and sometimes relate to beatings at the hands of women. The patient is hypospadiacal. His nervous affections are the common form of cerebral and spinal neurasthenia with agoraphobia, fearfulness, headache, spinal irritation with hypochondriacal paroxysms. This sexual pervert married a lady who attracted him through her qualities of mind and who on account of female troubles and probably weakened sexual instincts made no demand on his sexual qualities. Patient married, as he says, "to satisfy society," the mental qualities of the lady being congenial, but he wishes for a childless marriage that his pathological peculiarities may die with him and not be a curse upon future generations.

*Case III.*—Mr. Z., 36 years of age, bachelor, of high social standing; father was neuropathic and eccentric; mother nervous; brother showed signs of sexual perversion. Of ten brothers and sisters one sister is psychologically abnormal, two others dislike men and love women. As a child, was weak-limbed and of a nervous organization, fond of feminine work and play, no fondness for boys' games or hunting, and was laughed at and scolded for his feminine ways. At the institute he acquired the practice of onanism. At the age of 13 he formed a burning attachment for an elderly officer. From that time on he only cared for those of his own sex and then not for the young, but for those of riper years and robust form. Such men fascinated him; "women were no more to him than porcelain pictures." He "could see no beauty save in the male form and thought the bosoms and wide hips of women were unæsthetic and ungainly." At the galleries it was only male statues that pleased him; at the circus, male performers. At 16 he became desirous of looking at male genitals. After he was grown up his comrades took him to a brothel. He could not perform the act of coition from sheer disgust. Masturbation by woman produced ejaculation accompanied by sexual gratification. He felt immeasurably unhappy and melancholic when his family tried to draw him into a marriage, and felt as relieved from imprisonment when the lady married another. He only finds happiness by association with men. For many years he had suffered from neurasthenia, with severe headache, sleeplessness, genital irritation, hypochondriacal symptoms, etc., all of which he ascribed to the fact that he had been unable to satisfy his sexual desires, and to onanism, which he had practiced as a substitute. Sexual satisfaction was obtained by kisses and embraces with a man, especially if the man lay on him. Every ten or twelve days he would experience these desires, and if he could not satisfy them he became nervous and irritable and had all sorts of nervous derangements. He felt in fact like a woman in the sexual act. His highest idea of pleasure was passive pederasty, and in Italy he once attempted it, but disgust prevented him from completing it; it reminded him too much of coition. His highest happiness would be a sort of marriage with a beloved being of the male sex. The few erotic dreams which he experienced had for their subject men. He was unhappy, not only because of his abnormal sexual position and the resultant nervous disorder, but because he feared insanity as a result of his troubles. The constant fear that his secret will be discovered and his social position thereby destroyed makes his whole life miserable. He dare not be a father lest he should bequeath to his children his own abnormal nature. Patient is an intellectual-appearing man, of strong masculine build, with heavy beard, showing no abnormal appearance and having nothing feminine about him, either in his manner or his dress. An expert would remark the extremely neuropathic eye. The nose is unusually large. The upper teeth are somewhat decayed. The skull measures 53 centimeters. The pelvis and genitals are normal.

*Case IV.*—Herr von Z., a Pole, age 51, neurasthenic since 17. Mother was not mentally normal. She hated her children and loved her dogs. At cadet school he acquired the practice of onanism. He developed normally, sexually and otherwise; enjoyed sexual intercourse with women until he was 25 years of age; married a congenial lady; acquired at 26 serious nervous complaints, and developed a fondness for those of his own sex. He was compromised in a treasonable plot and sentenced to five years in Siberia. There his condition was aggravated as the result of continued masturbation. When released at the age of 35 he was suffering from

cerebral and spinal asthenia, dyspepsia, hypochondria, trembling, morbid anxiety, spinal irritation, nocturnal emissions, etc. He then sought relief at the watering places and medicinal springs, but failed to obtain it. His abnormal sexual feelings were in no way changed. He lived mostly separate from his wife, for whose mental qualities he had a high regard, but toward whom, as a woman, he was as indifferent as toward all other women. His otherwise pronounced fondness for those of his own sex was entirely Platonic. He was satisfied with their friendship and with hearty kisses and embraces. Whatever lascivious dreams he had, had those of his own sex for their subjects. While awake, too, the sight of well-formed handsome men would cause erections and ejaculations, while the most beautiful women had no effect upon him. At times of great excitement he would have erections at the sight of even male statues. At the circus or in the ballet it was only the men who interested him. He considered his perverted taste as a physical malady, without being rendered unhappy by it. A course of common faradization restored this man to his normal sexual condition.

*Case V.*—Herr Y. Z., 29 years old, a real estate owner in Russian Poland. Grandfather had melancholia and died suddenly at 47; mother neuropathic, of a neuropathic family; brother committed suicide; a cousin showed perverted sexual instincts. For generations the family has intermarried. The patient has had scrofula and headache, and a cerebral injury. At 13 he began onanism. A few years later he acquired severe cerebro-spinal neurasthenia, with irritable genital weakness and frequent pollutions. His nervous troubles have increased and hypochondriacal symptoms have appeared, with delusions of persecution. Has since childhood had a Platonic fondness toward males, and since the age of 9 years had frequently been in love with them. At the age of 20 he began to feel a longing for sexual connection with men; old men of about sixty. The female sex had no attractions for him; never realized any passion for sexual commerce with them. In order to alleviate the effects of self-pollution, he had at times attempted, under medical advice, to hold sexual intercourse, but he found himself impotent. His pleasure was only in intimacy with men. In his weak sexual condition a kiss or an embrace was sufficient to produce an erection and ejaculation; later he had become so excitable that the sympathetic pressure of a man's hand was followed by an emission. He found himself, therefore, compelled to withdraw from the society of men. At Gratz he formed a Platonic attachment for a student and a bath attendant. At Venice he fell in love with a 19-year-old youth and made him his mistress. Their sexual intimacy consisted in kisses, embraces, and the handling of the other's genitals. He never went as far as pederasty. He formed other similar attachments, caused a scandal in the hotel, and was obliged to leave Italy. So long as he could satisfy his sexual desires the neurasthenic symptoms disappeared entirely and the delusions regarding persecutions remained dormant. When he returned home, where he could not satisfy his sexual desires, there was a recurrence of neurasthenia and delusions, which finally obliged his removal to an insane asylum. Herr Z. is of a muscular and wholly masculine appearance. The left testicle is not descended. Otherwise the genitals are well developed; hair and beard abundant; voice manly; demeanor shy, but in no way offensive.

*Case VI.*—Miss X., 38 years old; had severe spinal irritation and chronic insomnia. Her mother was of a nervous organization; the rest of the family apparently healthy. Her sufferings dated from a fall upon her back received in 1872, which caused the patient a severe shock. In connection therewith there developed neurasthenic and hysterical symptoms, with severe spinal irritations and insomnia. Episodically there was hysterical paraplegia of eight months' duration, and instances of hysterical hallucinatory delirium with convulsions. In addition there were symptoms of morphinism. The patient attracted attention by her clothing features, man's hat, short hair, spectacles, gentleman's cravat, and a sort of coat of male cut covering her woman's dress. She had coarse male features, a rough and very deep voice, and, with the exception of the bosom, of a female and contour of the pelvis, looked more like a man in woman's clothing than like a woman. During all the time I had her under observation there were no signs of eroticism. As a child she had fondness for horses and masculine pastimes, but never took any interest in feminine occupations. She later developed a taste for literature, and sought to fit herself for a teacher. She never enjoyed dancing, and the ballet had no interest for her. Her highest enjoyment was to go to the circus. Up to the time of her sickness, in 1872, she had no particular fondness for persons of either sex. After this there developed in her an attachment toward women, especially young women. She was never passionately aroused in her intimacy with them, but her friendship and self-sacrifices toward those she loved was boundless, while from that time on she had an abhorrence for men and male society. She had an offer of marriage in 1872, but refused it. She took a trip to a watering place and

returned entirely changed sexually, and made use of expressions which implied that she would only associate with women, had love affairs with them, and let fall insinuations that she was a man. While she was at the baths, in 1874, a young woman fell in love with her, thinking she was a man in woman's clothing. When this young lady afterwards married, Miss X. became very melancholy and complained of faithlessness. Her friends noticed that after her sickness she evinced a decided preference for male clothing and a masculine appearance, while before her illness she had been in nowise other than a womanly character, at least as regards her sexual feelings. The patient was carrying on a purely Platonic love affair with a young woman and wrote her tender love letters.

The following additional references to the literature may also aid the jurist and the medico-legal, neurological, and psychiatric expert in the study of particular forms of this moral pestilence: Hoffman<sup>1</sup> states that tribadism in places of imprisonment for prostitutes is frequent. Andronico<sup>2</sup> found tribadism frequent in similar institutions in Italy. Kiernan<sup>3</sup> found it relatively frequent among the female insane in the overcrowded (five patients to two beds) female wards of the Cook County Insane Hospital. Lombroso<sup>4</sup> states that tribadism has been far from infrequently observed in Italian insane hospitals. It is often introduced by nymphomaniacs, sexual perverts, pubescent lunatics, hysterics, and imbeciles. The clitoris is often found enlarged in the degenerate and the pubescent. Tribadism is frequent in the Turkish harems. Sometimes it originates in the delectable tastes of the male owner. Moll points out that tribadism may develop into sexual perversion through the association of the manipulator or manipulated with the orgasm. Kern<sup>5</sup> takes the ground that the forensic relations of perverse sexual instincts should be determined by the individual in whom these are found rather than the perversion itself. Lord Audley (Howels State Trials, 3, 401), found guilty of pederastic rape on his wife, was executed. He was a sexual pervert, but exhibited no other evidence of insanity. Legrave<sup>6</sup> has reported a lad of degenerated parentage addicted from an early age to masturbation. At school pederasty was learned. He liked to dress in girl's clothing and play with dolls. He had at the age of 16 his first attack of grand mal. He was sent to an insane hospital at 17. Nana, of Zola's romance of that name, was a tribadist and far more jealous of Saten's relationship to other women than of any of her lovers. Dr. L. B. Allen,<sup>7</sup> of Humboldt, Nebr., reports the case of a donkey kept for breeding purposes, which was unable to copulate unless a can were present. Dr. Caton<sup>8</sup> has reported similar cases among animals.

P. S.—I might have included in the context a record of a mild form of intermediate perversion in the person of one of my servants, a colored male creole, who has more womanly than manly attributes. He is 5 feet tall, slenderly built, has large, full eyes, round, symmetrical head, and rather broad hips. Though his mouth is encircled with a growth of short hair which he never disturbs with a razor, he delights in wearing his hair as long as it will grow, and it is several inches long behind and not curly, as it is in front. He wears by preference a woman's high-heeled gaiter button shoe, size 5½, and in the discharge of his household work, waiting on table, etc., he prefers a woman's long white apron, extending clear round his body, to any other form of apron, and wears a white jacket under it. He looks for all the world, when fixed up to his taste, like a woman from the chin downwards. His face is effeminate; his tastes for work are all that way; likewise his voice, though when strained in trying to sing it is often falsetto. He has a special fondness for ribbons, flowers, and kid gloves, admiration for queensware and woman's dresses, keeps a picture of himself and a male friend but no female friend in his room, decorates the rocking-chair in his room with

ribbon, is fond of perfumery, parts his hair in the middle, keeps his wife's clothing and has many things in his possession which are peculiar to women, and makes the impression of a woman about the house in his walk, his talk, and his ways; has been married, but says women are frauds, yet in strange incongruity shows plainly in so many of his actions that he would have been a woman if he could.

### ADDRESS OF THE PRESIDENT OF THE SECTION, M. H. FLETCHER, M. D., CINCINNATI, OHIO.

LADIES AND GENTLEMEN: In behalf of the officers of this section of the Pan-American Medical Congress I tender each and every one of you a hearty welcome. To our foreign guests I would say, that in consequence of the recent amicable arrangements between all American nations we claim you as brothers and greet you as such. This initial meeting of the Pan-American Medical Congress is an era in dentistry which finds it on a thoroughly founded footing as a profession, fully self-sufficient in many respects; at the same time not differing from other

sciences, in that it depends largely upon several others for its existence, for the attainments of one science makes others possible. After mechanics, dentistry depends upon nothing else so largely as upon medicine and its specialties. The greatest advancements known to medicine have been brought about through revelations by the microscope, and advancements from the same cause have been known to dentistry. Either of these sciences (according to the standard of to-day) would be quite primitive without the recent scientific improvement in the microscope. What would dentistry be to-day without delicate and accurately made instruments with which to carry out its conceptions? Will any dentist dare to say he can treat his patients intelligently without a scientific knowledge of mechanics or of physiology and pathology. He can no more justly say this than other specialists in medicine, for the object of each and every specialty is to repair or restore to usefulness some impaired or lost organ. When dentistry can be separated from the human anatomy then it can be called an independent science; but until then it must be a specialty of medicine, for these two professions only exist in consequence of the diseases of mankind. If it were possible for one to attain to the utmost limits of recorded knowledge and to add to this the experience of a long life of accurate observation, with a memory to retain it all, he would still have made only a beginning in that great school of truth by which we are surrounded. Now, if we divide even recorded truths into various branches of science, are we not culpable when we offer advice and administer remedies for the ills of our fellow-beings if we fall short of our utmost endeavor in gaining knowledge in one small branch? Dr. Hunter McGuire, in his presidential address at the last meeting of the American Medical Association, said: "No physician is fairly discharging his duty who fails to seek information on all these subjects and to take advantage of the knowledge offered him, and he is criminally negligent if he fails to act upon these foundation principles when the occasion arises. The eye can not say unto the hand, I have no need of thee; nor again the head to the foot, I have no need of thee." No more can medicine say unto one of her specialties, I have no need of thee; nor the specialties to medicine, I have no need of thee. What constitutes medicine or the science of medicine? It is knowledge of the truths relating to the health and disease of mankind and the administration of appropriate remedies when disease is present. Then is not surgery a part of medicine and the amputation of a limb or the opening of the peritoneal cavity for the removal of a pathological growth an appropriate remedy? Is not the removal of a tooth a part of surgery and the treatment of diseased teeth comparable to the treatment of the eye. When it comes to the supplying of an artificial limb, is it any more prosthetic surgery than the supplying of an artificial tooth?

These questions seem too self-evident for discussion, and would not be presented here but for the fact that some of our profession have taken that position, that dentistry is not a specialty of medicine. But has dentistry attained the position of a science? Let us see: Science is "truth ascertained," and dentistry, in order to be a science, must be able to show to others some truths peculiar to itself, discovered by virtue of the laws governing its demands; and we think it has done this for the following reasons: (1) The loss of a part of the human anatomy can be artificially restored and made useful by its being retained in position by atmospheric pressure. (2) That in other cases lost organs are imitated and placed permanently in position by being fastened to a part of the human anatomy. (3) That the loss of a part of an organ can be permanently restored with indestructible material. These three discoveries are peculiar to dentistry, and demand for it recognition as a science. But these three things can not exist without following the laws of mechanics, or be practiced intelligently without a knowledge of physiology, pathology, and anatomy. Here is a demand on four different branches of science.

The discovery by a member of our profession that caries of teeth is due to bacteria marks a great stride in the science of bacteriology, but as yet no germ has been discovered peculiar to the decay of teeth. These germs can all be found in other parts of the body and may thrive equally well in other places; but the discovery of the part they play in the loss of the teeth enables us the more intelligently to battle against their ravages. The same enemies and the same methods of their destruction obtain in other diseases and other parts of the body as are adapted in the teeth. The same principles of pathology and physiology obtain about the teeth as to other parts of the human frame, and can we say that dentistry has no part with medicine when these facts are before us? If so, a surgeon or dermatologist could as well take the same position. The principles involved in the loss of the teeth are identical with those by which other organs of the body are impaired or lost, and the only novelty about dentistry is the manner in which these organs are repaired or replaced; but it must adapt many principles from other sciences, the same as do other sciences and branches of medicine. The grinding and adjusting of lenses for the various forms of astigmatism require equal if not superior skill to that of fitting an artificial denture. Every oculist is supposed to know how to direct the optician in the principles of adjusting a lens to his patients' needs, but how many oculists are educated in the art of lens making? On the other hand, every dentist is supposed not only to know what his patients need, but also to know how to manufacture the article itself. Many people go to an optician to buy a pair of glasses which remedy the defects of sight to a certain degree, yet no optician pretends to call himself an oculist or a specialist of medicine because he can fit glasses to distorted sight; no more should a man be called a dentist simply because he can make and adjust a set of teeth. The word dentist should imply more knowledge even than the word oculist or gynecologist, for the reason that a dentist should first have an equal medical knowledge to that of any other specialist; and in addition to this he should be a skilled mechanic, capable of manufacturing and adjusting any device demanded by his patients' needs; and there being no two cases identical, he should be versatile enough to adapt foundation principles to any variety of combinations; and, lastly, he should be an artist of sufficient taste and skill to reproduce nature in his specialty in her most attractive forms, for in the teeth and lips we read much of character; we are either attracted or repulsed by the expression of the mouth, and read strength or weakness in the teeth. Now, when these points are in the hand of man to be reproduced, he must needs be an artist, an anatomist, and a mechanic who can suit the new anatomy to the old with perfect harmony. Does any other specialty of medicine demand so much? As a profession we are dignified by having special legislation governing our practice; and these laws are looked after by examining boards in most of our States. We also have numerous colleges scattered through our land for the education of persons intending to practice this specialty. Why are we thus guarded? Because all our operations are upon and deal with the life, health, and comfort of our fellow-men. Does general medicine or any of its specialties demand more? The facts of the matter are that, whether we will or not, or whether the medical world will or not, dentistry is one of the greatest and most important specialties of medicine, and this too without having mentioned oral surgery as surgery, which many of the members of our special branch practice with unsurpassed skill.

The diseases of the mouth are seldom epidemic, but is not this cavity the vestibule through which many of our most dreaded diseases enter the body? The mouth is constantly inhabited by a number of varieties of bacteria, and is a most perfect incubator for many disease germs, furnishing them proper food and environment for their rapid increase. The condition of the mouth and teeth certainly has a great effect upon the general health in many ways. Hence the need of skillful

and intelligent specialists in dental surgery. The highest skill of the medical world to-day is exerted in efforts to prevent disease, which is equally true in the specialty of dentistry; but with high skill and the greatest of care many mistakes are made. A physician may mistake in diagnosis and be entirely at fault with his treatment; nevertheless, the patient may recover in consequence of nature's tendency to follow natural laws. On the other hand, however, by far the largest per cent of the operations of a dentist are as apparent in their result to the patient as to the practitioner, so that we must be conscientious, careful, and accurate, for there are few excuses for mistakes in dentistry like there may be in the treatment of obscure diseases of hidden organs in other parts of the body.

Dentistry having reached its highest attainments in the United States, we, as an association of practitioners, represent dental opinion from all sections of the world; so let us be careful to take no position which does not represent good judgment and careful thought, supported by scientific truth. As to examining boards in all branches of medicine, I hope to see the United States in the near future in the same position with some European countries, in that the colleges educate, while independent and impartial examining boards pass on the attainments of a student.

Before closing this address I wish to speak of my appreciation of the honor shown me by having been selected to be your presiding officer, and to render my thanks to my fellow-members for the honor and for their loyal support. When I recall the high standing and attainments of so many of my confrères and associates I feel keenly my own unworthiness and beg your indulgence for my shortcomings. Lastly, in the questions proposed, the papers to be read, and the discussion to follow at this meeting, let us so conduct ourselves that the world may see our main object is to ascertain the truth, and that we are free from bigotry and conceit, for these latter traits are not accompaniments of true scientific research. We do not have to argue the question as to our position, but naturally take our proper place both in the scientific and medical world, and are classed among the people of greatest usefulness and highest intelligence.

---

#### DISCUSSION.

In response to requests for the members to discuss the points touched upon by the chairman's opening address, Dr. J. Taft said that he was glad that such a paper had been presented on the opening of the section. He approved the views of Dr. Fletcher as to the status of the dentists with relation to the medical profession, and he was glad to note that it was becoming more and more generally held that dentistry was a branch of the great healing art. The feeling is expressed more frequently than ever before that dentistry is a specialty of medicine, but still there are many, including even some of our teachers, who hold that it is a mere mechanical art, or if not this, that it is a profession of itself, apart from that of medicine. It seemed to him that nothing could be plainer than that in all material points dentistry is a part of the practice of medicine. The principles that govern in dentistry are the same as those which underlie medicine in general. Ignoring of this fact ministers to the egotism and self-aggrandizement of those who hold that dentistry is a great profession of itself, which they claim they themselves have created. How does it differ from general medicine? It treats diseases of the same human body, and for the means of alleviating these diseases it depends upon the same courses of treatment in general governed by the same science, the same knowledge, and the same principles of nature. It seems that the day is quite past when this question should be disputed. There is nothing to be gained by having it a separate profession—everything to be gained by considering it a part

of the great profession of medicine and making tributary to our success all the investigations, science, and resources of medicine.

Dr. Jacob L. Williams, of Boston, expressed his satisfaction with the views of Dr. Taft. He felt that dentistry, or as he preferred it should be called, "oristry," expressing the best comprehensive practice, was a specialty of medical science. Perhaps this view was partially because he had originally been educated in dentistry as a specialty of medicine. He said that if we look back we will find that its origin was from medical men, and the science on which it is based we owe to medical practitioners. The facility with which many of the operations may be taken up and performed by the aid of mere mechanical skill and aptitude, and the applause with which mechanical success had at times been received, gave rise to the feeling that it was rather a mechanical pursuit than worthy to be classed as a learned profession.

Dr. S. B. Brown, of Fort Wayne, Ind., said that it seemed proper that we, in a section of the Pan-American Congress, have assumed that dentistry was a specialty in medicine, but, nevertheless, we stand as dentists and take pride in the advance the profession of dentistry has made.

## PAPERS READ BEFORE THE SECTION.

### PULPLESS TEETH AND THEIR TREATMENT.

By GEORGE EVANS, of New York.

It is doubtful if dental literature presents another subject on which so much has been written with so great diversity of dissenting views as that of pulpless teeth. This is equally true whether as regards the description of the conduct of operations for the prevention of possible lesions or the prescription of remedial treatment for the cure of existing troubles. As almost universally accepted principles govern these matters it is in the details of methods of procedure and therapeutics that these diverse opinions are found to exist. That admitted uncertainty or questionable positiveness to some extent characterize their discussion in almost every case is evidenced by the text-books of our profession and by its periodical literature and clinical reports. A general contemplation of the subject under these circumstances is at times apt to be somewhat confusing as well as surprising when we see such expressed divergence of opinion coming from those most eminent as practitioners. In view of these facts, therefore, in presenting before a body such as this a paper on pulpless teeth, which must necessarily discuss so many disputed points, I feel conscious that I have undertaken a difficult task, and one which might be deemed presumptuous should I assume to be able to enlighten you in an extraordinary degree or to entirely harmonize your opinions. I shall endeavor to present for your consideration, discussion, and criticism an intelligible conception of the subject, embodying a liberal valuation of points in treatment, based as much as possible on science instead of empiricism, and practical experience rather than theory. I shall hope thus to assist in arriving at conclusions which will be ultimately universally recognized as correct in surgical procedures and most suitable in therapeutic treatment.

A pulpless tooth is understood to be a tooth with a non-vital pulp, or one from which the pulp has been removed with consequent loss of vitality of the dentine. Respecting the remaining structures of such teeth we have one of two conditions presented, the first where the vitality of the entire cementum is retained, the other with non-vitality of a part of the cementum on the side of the root, or of the portion constituting the apex, through the action of devitalizing agents or the presence of some lesion. Independent of other pathological conditions present, according to the degree of existing vitality as contributed by the connective tissue, the pericementum, favorable effects of treatment may be expected and permanent results assured. The treatment of pulpless teeth or roots for the prevention of future trouble or in connection with the cure of existing lesions consists in as thorough a performance as possible of the following operations: (1) Removal of the contents of the root canals; (2) disinfection of the root canals and dentine, and the establishment of permanent aseptic conditions by mummification of the contents of the tubuli; (3) closure of the apical foramen.

#### PREPARATION OF ROOT CANALS.

A knowledge of the usual positions, forms, and variations of the roots and canals in the different teeth is essential for a generally successful performance of this operation, which is greatly facilitated by obtaining direct access to the root

canal by a proper removal of the tooth structure. This in a lower molar is illustrated in section in fig. 2, a. The slot in the occluding surface, it will be seen, is sufficiently extended to give direct access to the canals of both roots; an approximal decay requires similar extension (b). In the incisors enough of the palato-approximal wall should be removed to allow instruments to be used with the least possible curve, as shown at c, fig. 2, in a central incisor. Should this, in the opinion of the operator, involve too great a loss of tooth structure, a small hole can be drilled in the palatal side, as seen in fig. 3, and direct access to the canal thus obtained. The drilling of holes such as these is best confined to centrals, as if they are made in laterals and both approximal sides should, at some future time, decay, the palatal wall is seriously weakened by the loss of so much of its structure, as shown in fig. 3. In molars, when cervical decay of moderate extent involves the vitality of the pulp and the contour of the coronal section is only slightly encroached upon, an independent entrance to the pulp cavity had best be made in the center of the occluding surface for the treatment of the root canals, the cervical cavity being filled separately. The principles here outlined can also be applied to cuspids and bicuspid. In crown work on the anterior teeth the removal of the coronal section directly exposes the pulp cavity.

In preparing bicuspid and molars for all-gold crowns the leveling of the occluding surface and removal of a portion of the side most involved by decay should be preliminary. A proper opening having been made, any remaining portion of the pulp is removed with broaches. A few fibers of cotton should be twisted around the serrated portion of the broach to allow of easy removal in case of breakage. The canals are then, guided by frequent explorations with a fine probe, carefully enlarged with Gates Glidden drills. At least three sizes of drills, large, medium, small, are required, each for the right angle and the direct hand piece. Very little, if any, pressure should be put upon them when in motion, as they will move forward sufficiently of themselves. Under pressure the formation of a false passage in a curved root is possible, or the small drill might be broken off or forced through the apical foramen with disastrous consequences where alveolar abscess did not exist. Neither should drills be forced into a canal closed by calcification, nor into the canal beyond the line of the apical cementum, nor through a constriction which a fine flexible probe can not enter, nor around a curve sharp enough to be unsafe to pass. A slight pain, of which the patient should be instructed to notify the operator, is experienced when they enter the zone of cementum which composes the end of the root, if its vitality has not been impaired by improper use of arsenic in devitalization of the pulp or by alveolar abscess. The probe-like points of these drills do not cut, but simply guide the drills and confine them to the line of the canal. They should be gently given a constant slight forward and backward motion in the canal, and treated more as reamers than drills. Unless thus used the coarse serrations of the head of the drill may fasten in the canal, when the head is liable to be broken off. The occasional quick withdrawal of the drill from the canal during the process of drilling will aid removal of the débris.

The depth to which a canal may be enlarged or reamed is regulated by its actual length and previously ascertained condition, and the diameter of the enlargement by the shape and dimensions of the root. The use of these drills is condemned by some operators for reasons properly attributable to their careless or improper employment, but they are indorsed, in experienced hands, for their adaptability to the work under consideration. They should be frequently sharpened with a suitably shaped Arkansas stone. The shank just back of the head should be large enough to assure strength. The temper should be such that the steel might be bent but not broken, even though the edges of the serrations become sooner dulled in consequence. The Palmer root-canal excavators also will be found serviceable to open up a canal and enlarge it in accordance with its original shape. The

reaming of a canal not only simplifies the operation of filling, but also opens up the ends of the tubuli, and facilitates the permeation of the dentine by antiseptic agents, the advantage of which must be admitted when a septic condition is present. Under favorable circumstances the line of the zone of cementum at the end of the root is a safe point to ream to and stop at.

I am aware that some few operators state that they do not ream out root canals, but claim to treat and fill them as well as those who do. Careful investigation of the subject seems to demonstrate that the majority even of these, in obtaining an entrance to a canal, enlarge the orifice and to some extent really ream out the canal. The reaming, then, is with them only a matter of extent. I also find, as a rule, that in proportion as root canals are properly, I do not mean excessively, reamed and opened up, so are subsequent operations on them satisfactorily performed.

In the treatment of alveolar abscess the canal should be enlarged as already described and the foramen, if possible, opened up with a smooth broach instead of a drill. Drilling through the end of a root or extensively into the cementum at the apex is to be condemned, except when it is desirable to afford immediate relief to the patient in cases of acute abscess. In chronic alveolar abscess the immediate or more prolonged action of agents sealed in the canal for a day or more, for the purpose of disinfection, will usually facilitate the passage of a broach or permit peroxide of hydrogen to be forced through. When this is not the case, a fractional part of a drop of aromatic sulphuric acid, held in position in the end of the canal on a few shreds of cotton for twenty-four hours, will usually effect an opening unless exostosis exists. My objection to attempting to drill through a foramen is that although the main line of the canal may be straight or nearly so, the extremity of the root to some extent curves in a large proportion of cases, a condition impossible to always determine, and as a sharp-pointed drill has to be used, it will move rather in a straight line than a curve, so that a passage to one side instead of through the foramen is likely to be made. This leaves the apex in a form not conducive to successful treatment unless a burr is subsequently introduced externally into the region of the abscess, and that part of the apical section of the root removed. (Fig. 4.)

#### THERAPEUTIC TREATMENT OF THE ROOT CANALS.

Pulpless teeth are presented for treatment in either of the four following conditions: (1) Where a healthy or non-putrescent pulp has been extirpated from the canals; (2) where on opening into the pulp chamber it is found empty and dry, with the pulp mummified, or the root canal calcified and the root externally in a healthy condition; (3) where a pulp is found in diseased or putrescent condition; (4) where alveolar abscess is present and a septic condition of the canals and dentine exists.

In the first and second classes the treatment should be directed to assuring a continuance of the existing aseptic condition and as immediate as possible filling of the canal; in the third and fourth classes to bringing about an aseptic condition by disinfection and sterilization and making certain of its future maintenance, including incidentally the cure of any existing disease of the external membrane or of the alveolus. In cases of the first and second classes water and saliva should be excluded from the pulp chamber and canals during their entire preparation and filling. The instruments should be sterilized, and the broaches, if serrated, had better be new. In the third or fourth classes exclusion of saliva or water is not necessary in the preliminary work on the canal; water may be freely used until the process of disinfection and sterilization is commenced. Then and thereafter its entrance must be prevented. To this end the rubber dam should be applied if practicable. When it is not, as frequently occurs with roots and teeth

badly affected with cervical decay, other means of keeping out moisture should be resorted to. In such cases, during each interruption in the operation, the entrance to the canal should be filled with absorbent cotton saturated with a suitable essential oil or antiseptic fluid, and saliva thus excluded. After the canal has been properly opened up and its contents removed, it may be washed out with peroxide of hydrogen and wiped out with absorbent cotton.

The next point in the conduct of the operation is to secure as thorough a state of dryness in the pulp chamber by the use of air at a temperature higher, as it leaves the nozzle of the ordinary or the A. S. Richmond hot-air syringe, than is comfortable for the finger. A root-canal dryer, with the end tapered as fine as a broach at the point, is then introduced into the canal. I prefer the form in which the point is made of silver and the bulb portion of copper. As silver possesses remarkable properties as a thermal conductor, the heat is transmitted to the point of the probe very rapidly. The probe being inserted as far as possible up the canal, the patient is directed to raise the hand as a signal should the heat cause pain, when the probe must be moved up and down or withdrawn for a moment. This procedure, following the previous application of the hot air with the syringe, evaporates the moisture and aids the escape of any gases present in the root canals and the open ends of the tubuli. The point of the root-canal dryer acts as a sterilizer and may be applied so hot as to carbonize any organic matter it reaches in the end of the canal, a portion of which can each time be removed on its point. As the silver point can be tapered as small as the finest broach, canal contents which it has been impossible to remove may be reached or rendered inert. In cases of the third or fourth classes, sepsis being present, the heat is very serviceable, as it aids the escape of gases from the canal and dentine and acts as a germicide. When in this dry and heated condition the dentine is in the best possible state for the application of antiseptic agents.

The suitability of various antiseptics in the treatment of tooth structures, their effectiveness and permanency when so used, singly or in combination, are subjects on which great diversity of opinion exists, and which have of late been made the object of clinical study and scientific investigation and discussion. Many antiseptics in common use, being coagulants of albumin, obstruct the dental tubuli, and consequently limit or retard diffusibility throughout the dentine. This is the objection to the use of carbolic acid, creosote, and like agents, additionally to which may be named their inefficiency to accomplish in certain conditions the end sought, and as well their eventual absorption from the dentine. Recent investigations seem to give preference to such antiseptics as are non-coagulative in their action. Of this character are the essential oils, many of which, according to Miller, Harlan, and others, possess antiseptic power much greater than has been commonly attributed to them. Acidulated solutions of bichloride of mercury, peroxide of hydrogen, the new agent sodium peroxide, especially in preliminary treatment, and various preparations of iodine, which exert chemical action and retain antiseptic properties for a great length of time.

The selection of antiseptic agents is important and is indicated by the conditions presented in a pulpless tooth. Cases in which a healthy pulp has just been extracted, or in which the canal is aseptic, are different from those with septic dentine or diseased or putrescent pulps. In the first-mentioned condition, with or without antiseptic treatment, favorable results usually follow root filling, the advantage of a reliable antiseptic agent in the canal being only to better insure the continuance of a state of asepsis. In the second condition the state of the dentine, and consequently the treatment to be effected, are entirely different. We need the action of agents that will not only destroy ptomaines, but exert a chemical action on sulphuretted hydrogen and other ethereal ammoniacal gases, the products of putrefaction, and entirely eliminate them. On this depends the successful treatment of such cases,

as the pressure and expansion of these gases are a certain cause for constant peridental inflammation, and so long as they are present in the slightest degree in a canal it is in an unsuitable condition to be closed. Carbolic acid, creosote, or the essential oils in such a condition exert no chemical action on these gases, merely disguising their odor, though by repeated dressings of cotton saturated with these agents the gases are absorbed by the cotton and to an extent slowly eliminated. What is required is the action of agents whose elements possess an affinity for these gases and will immediately decompose them, forming new combinations and entirely destroying the character of the gases.

Regarding the use of agents in the treatment of septic dentine of pulpless teeth, Dr. W. F. Litch, in a paper published in the Dental Cosmos, February, 1882, says:

In this respect a careful discrimination must be made between the powers, respectively, of such antiseptics as carbolic acid, creosote, oil of cloves, oil of thyme, etc., and such other antiseptics as chlorine, bromine, and iodine, which, in addition to their antizymotic power, are true chemical antagonists of those sulphuretted hydrogen compounds of which putrefactive gases are constituted, such gases being immediately decomposed by them; their hydrogen element going either to chlorine, bromine, or iodine, to form, respectively, hydrochloric, hydrobromic, or hydriodic acids, the sulphur being in each case precipitated. \* \* \* An antiseptic agent, as carbolic acid, can not be said to be a true disinfectant in the sense that all the products of putrefaction are decomposed by its presence. No matter how thoroughly the odor of putrefactive gases in a room or in a tooth may be masked or disguised by the characteristic odor of carbolic acid, creosote, oil of cloves, or, indeed, any antiseptic oil, the gases are none the less present, although their odor is neutralized; the disinfection is only apparent, not real. The further formation of putrefactive gases may be prevented, but the decomposition of those already formed must be accomplished by those chemical agents already cited.

I bring the facts respecting these agents emphatically to your notice, as I am conscious that a large proportion of practitioners at the present time still entirely adhere to and depend on carbolic acid or creosote exclusively for the treatment of the conditions presented in pulpless teeth. In accordance with these principles the use of iodine is indicated, and preference is given to its use in practice to that of the other agents mentioned. Its effects are best obtained from some one of the preparations now in use; aristol, for instance, its odor being entirely unobjectionable, in a strong solution in one of the essential oils. In my practice I favor the oil of cloves, cassia, and eucalyptus. I consider the oil of cloves more sedative in action than the others. I make it a point to flood the canal with the solution, thereby to some extent saturating the heated, dried dentine as well as the cementum at the apex. A more effective saturation can be accomplished by again drying and heating the dentine and applying the solution, or by filling the canal with cotton saturated with the solution, hermetically inclosing it and letting it so remain for a day or two.

I do not claim that coagulants, such as creosote or carbolic acid, are entirely non-diffusible in devitalized dentine or cementum, as decomposition or putrefaction effects elementary changes in the contents of the tubuli, but that their action is slow and limited compared to that of the essential oils. They have also the objectionable feature of being irritants and unsuitable where acute or chronic inflammation of the peridental membranes is present. I wish to mention this forcibly, for there are prominent men in the profession who advocate carbolic acid as the most suitable and in the treatment of alveolar abscess as the best remedial agent, declaring with great positiveness that the use of all other agents is useless and a waste of time. The history of the indiscriminate use of carbolic acid and creosote, in the practice of others and of myself, has convinced me that they are not in all cases and at all times suitable therapeutic agents to use. When a healthy pulp has just been extirpated and "immediate root filling" is practiced, the use of carbolic acid, creosote, or solution of chloride of zinc is best indicated, the condition then presented being entirely different from that where the pulp is

diseased or putrescent or the canal is in a septic state. When a healthy pulp has been removed, its minute fibrous connections with the walls of the canal and the vessels at the apical foramen are severed, and the action of an escharotic antiseptic agent, such as carbolic acid, is in fact then indicated, as it acts as a coagulant and instantly seals up the ends of the tubuli. If "immediate root filling" is not to be practiced, then the prescription of such agents as the essential oils, with aristol or iodoform, seems more suitable, as a slow but certain mummification of the non-vital organic matter it reaches follows. Moreover, the oils possess advantages over the coagulants mentioned in not being miscible with water, and thus being eliminated, so that by their use the antiseptic action is perpetuated.

From these statements it might be asked what special advantage is there in the much-discussed method of "immediate root filling" beyond that of the time gained by the operator? I would answer, that in the proper conduct of treatment there is none. A canal with an antiseptic dressing, with the orifice of the canal and cavity hermetically sealed securely with gutta-percha or oxyphosphate of zinc, is free from the danger of inroads of microorganisms or of the supervention of sepsis for a reasonable interval of time. The disadvantage of immediate root filling is that should some fragment of the pulp remain in the extremity of the canal it fails to receive the benefit accruing from the reapplication of antiseptics, which would better assure inertness by mummification.

In brief my conclusions are that in cases of pulpless teeth, where an aseptic condition of root canals and dentine exists and immediate root filling is to be practiced, the use of coagulants such as carbolic acid or creosote, alone or in combination with other suitable agents, is permissible; but when sepsis exists their use is contraindicated in favor of non-coagulants; that treatment with such agents should be followed and the filling of the root be temporarily deferred; that if alveolar abscess exist treatment through the apical foramen by injection should be restricted to the use of non-coagulants until disinfection of the dentine is effected.

There is such a thing as overtreatment, an unnecessarily frequent renewal of antiseptic dressing in root canals, thereby aggravating or producing irritation of the pericementum at the apex of the root. Such cases may be relieved by washing out the canal with alcohol, and applying the alcohol on the dressing instead of the agents previously employed.

#### CLOSURE OF THE APICAL FORAMEN AND FILLING OF THE CANAL.

The object of root-canal filling is to prevent the entrance of the fluids through the foramen and avert, in case of the formation of gases, irritation of the peridental membranes by their pressure or presence. Respecting this branch of treatment, I might say that there is no difference of opinion as to what ought to be done, but preferences exist as to the method of procedure and the materials to be used. Gutta-percha or oxychloride of zinc are generally accepted as the most suitable. Either gutta-percha in the form of chloro gutta-percha or the oxychloride of zinc, mixed thin, can be pumped or placed in the extreme end of the canal with the aid of a broach or fine-pointed probe. This is one of the advantages that commends the use of these materials. When the chloro gutta-percha has been placed in the apex the remainder of the canal can be filled with the prepared cones of solid gutta-percha until no more can be inserted. A current of hot air should then be thrown on the protruding ends of the cones at a temperature sufficient to soften them and warm the dentine, when they should be gently pressed but not suddenly pushed up in the canal. A slight twinge to the patient will usually be the signal of their complete impactment in the canal. The solid gutta-percha absorbs what little chloroform was present in the chloro gutta-percha and the heat also aids its evaporation, so that the shrinkage, so often urged as an objection against the use of

chloro gutta-percha, is reduced to a minimum. An advantage possessed by oxychloride of zinc over other materials is its antiseptic qualities; its disadvantage, the difficulty attending its removal from the extremity of the canal should supervening conditions require it. I frequently use it in combination with gutta-percha, filling the extremity and part of the canal with gutta-percha and then the orifice and pulp chamber with the oxychloride. Wood and metal shaped to fit the canal are also much used to fill root canals, but unless a small quantity of chloro gutta-percha or oxychloride of zinc is placed in the extremity or on the point used the entire closure of the canal is doubtful. The use of cotton as a filling in root canals is to be condemned unless it is sterilized or iodoformized and saturated with chloro gutta-percha previous to insertion. Asbestos by some is given preference to cotton. Tin or gold foil is difficult to insert without vacuoles. Paraffin in combination with a small quantity of aristol, as a material to fill root canals, has been suggested by Dr. Kirk, especially after the use of sodium peroxide. Sodium peroxide, being a most active solvent of albuminous matter, in a measure frees the ends of the tubuli or a canal of their organic contents, a condition favorable for the use of paraffin. Paraffin is aseptic and melts at a low temperature, and can, with a heated root-canal dryer, be flowed into the ends of the tubuli or a minute canal that was not considered safe to open up. Ordinary gutta-percha should be used to close a foramen when an abscess has just been treated by injecting through it. The length of the canal should be measured with a probe and gauged with a small perforated disk of rubber dam slipped upon the instrument. The gutta-percha should then be carried to position on the point and an allowance made for the displacement of the instrument. As oil of eucalyptus is a solvent of gutta-percha, the application of this oil alone or in combination with iodoform or aristol is recommended in the final treatment when chloro gutta-percha is not used, as better adhesion of the gutta-percha to the walls of the canal is thus obtained. In a case of chronic alveolar abscess, where amputation of the apical section of the root is to be practiced, oxychloride of zinc makes a most suitable filling.

It is not my intention to discuss the subject of alveolar abscess more than to say that, it matters not what form it may present, treatment primarily should consist in a thorough disinfection of the canal and dentine of the affected root, and finally the adoption of such measures as will maintain a state of asepsis.

I feel that I can not well close the paper without some comment on the method proclaimed by Dr. Herbst of treating pulps in teeth ordinarily classed as pulpless, and which has of late been given considerable prominence. The idea of this method is to devitalize with cobalt only the section of the pulp in the pulp chamber, remove it, and seal up the portion in the canal, adopting measures during the operation to maintain asepsis, as the pulp will then probably remain inert in case of non-vitality supervening. The object is to simplify and lessen the work on such teeth and retain some circulation in the dentine from the remaining vital pulp in the roots.

The objections to this method, briefly stated, are: (1) The action of cobalt or arsenic in the devitalization of a pulp is not controllable. (2) Even though the vitality of the pulp left in the root canals is retained an atrophied and then a non-vital condition is liable to follow; also, as a large percentage of exposed pulps are diseased, in such cases sepsis will supervene. (3) The method in result is similar to the operation commonly performed in which antiseptic measures are adopted, but lacks thoroughness respecting the treatment of root canals. (4) Its performance in detail, as described, would require in many instances as much time as the recognized method in practice. (5) Present recognized methods show an exceedingly low percentage of failures, and the practice of Dr. Herbst's method would commence an era of doubt and uncertainty respecting operations on pulpless teeth. (6) The introduction of such a method in the teachings of

the schools and elsewhere would have a tendency to encourage a lack of thoroughness in operations on pulpless teeth. I make this criticism with due deference to the investigations and statements of Dr. Herbst and respect to the gentlemen in this country who have advocated his method.

Having presented to you my conception of what I consider should be the treatment of pulpless teeth in accordance with correct scientific and rational principles, and as dictated by modern methods of practice, I might ask the question, Are these described operations always possible of perfect performance? We work at times under great difficulties, in places unseen, and we can not assert what is unknown. I consider it far preferable to suspend efforts to effect thoroughness in a root canal than to risk penetrating foramen or wall; better to fail to thoroughly impact the filling than force it through the foramen into the apical space. The former would be designated a failure; the latter would be a malperformance. Sound judgment counsels caution, which, with knowledge and skill, will, as a rule, insure present and future satisfactory results in these operations. To the educated, skilled dentist of the present day few pathological conditions of the teeth are uncontrollable, and in mechanical operations extraordinary results are possible of attainment. Treatment of pulpless teeth in accordance with the principles and methods advocated I believe will be classed among his greatest successes.

---

#### DISCUSSION.

Dr. Knapp, being called upon to open the discussion, said that he could commend the paper highly, though in some points his practice differed with that of the author.

Dr. Brown said that the subject of pulp-canal treatment and filling was one of great importance in practice, and we can not talk and think about it too much. Drilling out and enlarging the canal he thought not good practice; the better treatment was to take the canal as we find it. He had not much confidence in filling root canals with gutta-percha alone; but preferred gutta-percha with chloroform, as it could more surely be got to the apex of the canal. He had ceased to use gutta-percha points, as the solvent used in making the points was liable to soften it so as to make the filling imperfect. He preferred the use of copper or tin points, as with them he felt that he could make more reliable filling.

Dr. Noble said that in the main the paper agreed with his own notions in regard to the preparation of pulp canals, and certainly where the author deprecated the use of creosote and carbolic acid. The time was when these two drugs were considered a necessary part of the outfit of every dental office, when in truth one could not enter a dental office without being aware of their presence. He did not think the office should be saturated with these unpleasant odors; but thought that the essential oils with the peroxide of hydrogen and other well-known germicides were much to be preferred in use and much pleasanter. Of course, we still have iodoform, but with care, annoyance from its odor is not serious. He used aristol and eucalyptol oil in the preparation of root canals with success. He thinks oxychloride of zinc the best filling for canals; upon a shred of cotton it can be carried quite to the end of and thoroughly fill the minute crooked canals. He has but little faith in any filling in a canal so placed that it could be removed. He feels that the removal of any filling would cause irritation enough to make trouble and set up inflammation. He would sooner depend upon treatment from the outside rather than open up through the canal.

Dr. Jacob L. Williams, of Boston, did not agree with the paper in regard to the best material for filling the root canals. He thought that no matter how thoroughly or carefully a root canal is treated and filled, there was always a possibility of trouble some time in the future, which would necessitate the removal

for relief and treatment. It might be all right for a long time, even six, eight, or ten years, but then perhaps on account of a low state of health in the patient, an inflammation would set up, and it would be desirable to remove the filling for treatment. It was so nearly impossible to get out gutta-percha fillings that he did not feel it wise to insert them. His practice was to take rods of lead, zinc, tin, or copper, and having shaped them to fit the cavity, embed them in a mixture of tincture of benzoin with oxide of zinc. This paste will make a tight permanent filling. He allows the end of the rod to extend into the pulp chamber and turns it over after it is set in the canal and fills over it with gutta-percha. In case of necessity, it is easy to remove the gutta-percha, and then get hold of the end of the rod and draw it out of the canal. In regard to the oxychloride of zinc and the condition in which it should be used: The antiseptic qualities of oxychloride of zinc used to be depended upon for the preservation of the teeth whose pulps were endangered, but in many cases the teeth became discolored and upon removing the fillings the oxychloride was found not to be solid, but simply a mass saturated with septic matter. For this reason he had lost confidence in it as a permanent antiseptic, and uses oil of cassia or eucalyptol, or liquid paraffin, which is a vehicle for such antiseptics.

Dr. J. Taft spoke of the desirability of preserving the vitality of the pulps of the teeth, and the necessity of impressing both dentists and their patients with the importance of preserving their vitality. Our patients are very careless in this regard. It is difficult to make many of them understand that a living tooth is better than one with a devitalized pulp. If they would appreciate this as they should we would have fewer devitalized pulps to deal with. He had patients who had been under his care for years and years, who had not a devitalized pulp in their mouths, because they saw the necessity of watching their teeth and having them properly cared for in time. He would emphasize to all dentists the necessity of preserving the vitality of the pulps, and teaching their patients the importance of these organs. When a person has anything the matter with his eye he needs no promptings as to the necessity of having it promptly and skillfully cared for, as everyone feels the importance of sight; but a tooth is neglected till the suffering becomes unendurable, and then if it can only be relieved by the death of the pulp it is sacrificed, when, if treated in time, it might easily have been saved. It would be much better for the interest of both patient and dentist if the treatment was had in time. But do what we will, these pulpless teeth will come to us. The question is, What shall we do with them? Beyond and beneath the detail of management lie the conditions of each case, which must be studied. A tooth is presented to be put in the best possible condition. What shall be done with it? Deal with it as with a piece of metal? Not at all. The teeth are subject to different conditions, which must be understood. Some teeth are deteriorating, but will go on for years and years, and at last will be lost; others more rapidly will go from bad to worse and soon develop active disease. We should give attention to these varying conditions, because they affect the treatment which depends upon the susceptibilities of the living tissues. Some teeth may be very troublesome, and yet, because of strength and power of the system, they will recover and remain quiet. All these conditions will modify the treatment. When we have a dead pulp to deal with we must first free the canals and the tissues contiguous of everything that will cause disease. Remove mechanically all that is possible; what may remain neutralize and destroy with chemical or antiseptic means. Then close up the space with something that will not be an irritant to the tissues beyond. Keep out all that will produce poisonous gases and cause the trouble to recur. This should be so well done that there should not be any thought of removing the filling for re-treatment. If trouble should ensue afterwards, it will be because the operation was not

thoroughly done at first and an irritant was left, which will have given rise to abscesses. The better way, then, will be to penetrate to the root from the outside and cure the abscess so. The general principle in treating a pulpless root is to fill it up completely with metal, wood, or anything else that will accomplish the purpose. He spoke of his new preparation, pyrozone, and recommended the dentists to use it.

Dr. Williams said that the chief characteristics of a root filling were that it must be antiseptic and that it must completely fill the root canal. He spoke of operations of a surgical nature where, in after years, owing to a low vital state, trouble occurred at the seat of operation, and said that such trouble, under like conditions, was liable to occur in a tooth that had been devitalized and the canals filled.

Dr. Fletcher said that he realized that the subject had been pretty thoroughly gone over, especially as far as the treatment was concerned, but he wanted to speak of another difficulty with these cases. In surgery we have a definite treatment plainly indicated. If there is a sarcoma, or a tumor in the abdomen, we know they must be removed. And so in medicine there is a recognized lesion and a definite theory of treatment. Is this true in dentistry? Do we first diagnose the case correctly? Has anyone so defined these conditions that we can say this is periostitis or there is pus at the end of this tooth, and can we tell what is the cause of the trouble? He did not think it had been so well defined that we can discuss it as we should. When we know what is the matter we know what to do, but we do not have such perfect definitions as to understand how to discuss it. He hoped someone would take up the subject and systematically name the conditions so they would better know what they were talking about.

Dr. Taft said it would be difficult to do that, because the conditions were so various. It would be necessary to go to the very depths of the pathological conditions and the physiological conditions, and then it would be impossible to define them so that any other man would recognize them. It requires thorough knowledge of the conditions for each man.

Dr. Evans said that his paper, he thought, answered some of the questions brought up in the discussion. He had stated that a metallic filling would not, except in connection with some soft material like oxychloride of zinc or chloro percha, successfully fill the foramen. In regard to removing the filling, it is all right to fill so that it can not be removed if you could be sure it would not be necessary to remove it. If one could be quite sure of this, the plan of Dr. Morrison, which was to gauge a piece of wire the shape and length of the canal and mark the length with a notch cut in the wire, which would enable the operator to break the wire off at the notch, would be a good plan; but in case it was necessary to remove such a filling, it would be found almost impossible to do it. He thought the new preparation for clearing out pulp canals, sodium peroxide, an agent that will surpass anything we have heretofore had. It is a solvent, and opens up the canals and tubules in a wonderful manner. He thought with Dr. Fletcher, that the subject of the pathological conditions of the teeth had not been studied up as it should, and it would be well if the books described it better.

## PREPARATORY KNOWLEDGE FOR THE STUDY AND QUALIFYING EDUCATION IN THE APPLICATION OF PRINCIPLES FOR THE PRACTICE OF SPECIALTIES IN MEDICINE AND SURGERY.

By JACOB L. WILLIAMS, M. D., of Boston, Mass.

A highly encouraging indication of progress in general professional education, as well as in our special department, is the increasing appreciation of the importance of such preliminary knowledge and training on the part of the student as will enable him to comprehend accurately and readily the instruction given him in his professional pupilage. That this is essential to the best progress in study no one disputes, and it requires no argument. But there is another need which seems too much neglected, or too often only casually implied, in the course of the professional study intended to fit the student to practice. This need is in the matter of direct education in the general principles of medicine and surgery; that is, in the laws that govern the vital economy in health and disease, the knowledge of which, with the trained ability to apply it, is the only basis of the soundest practice. I say trained ability; for it is not common for the average student to recognize readily the correct relations and application of those general principles to the cases he may see in practice. It is only the few with special natural intuition that can do so without being constantly reminded of those relations by their teachers, by which constant training they may in time acquire a habit of such application. That skill in operation and manipulation is one essential no one questions; but if that is all to the neglect of knowing how and when to properly apply that skill, the student is only half fitted for practice, and that only by rote, as it were, as his skill is quite liable to be misdirected; and the axiom in engineering holds good here, too, that "the greater the skill misapplied the greater the blunder." This ability to discern principles in the application of skill distinguishes the professional practitioner from the simple mechanic, and those possessing it, with an ethical basis of character, may have no doubt that they belong to the great profession of ministers of nature in treating human ills.

When, in response to invitations, I sent to the secretary the synopsis of a paper that I hoped, but could not promise, to write out in full, I apprehended the pressure of affairs which has justified me in that provision. But I will say a few words that may perhaps make plainer the idea I wished to present. In regard to education as preliminary to the study of medicine and surgery, it is generally conceded that with the presumed mental training the more liberally equipped the student is in all knowledge having any bearing on his proposed professional study the more satisfactory will be his progress in that study. But with the best preliminary training we often find that the medical pupil needs reminding of the facts and principles the knowledge of which is supposed to be a part of his preliminary acquirements. So also when he comes to the learning of facts and principles that underlie the laws of health and disease, the average student most especially needs constant training in the relation of those principles to clinical or actual cases. This is what may be called qualifying education for practice of general or special medicine and surgery. Perhaps this qualifying need is at present most observable in regard to the practice of specialties, of which that of oristry is by no means an exception. With the ambition, laudable in itself, to excel in manipulative skill, how often do we see the unfortunate results of forgetfulness or ignorance of the principles that should direct or restrain that skill. To illustrate: It is well known that a heavy blow on the head is apt to produce paralysis of a longer or shorter duration. It is also known, I think first proved by the elder Agassiz, that from continuous lighter blows, the jarring irritation of the peripheral membranes of the brain, a similar result may follow. Ignorant of this fact or principle, a dental operator who prided himself on his skill in building up gold fillings with a heavy

mallet once subjected his patient, a man of fine nervous organization, to sessions of several hours a day for five consecutive days in building down the six upper front teeth, with the result of paralysis of the patient, from which he only partially recovered, and from which he died in about two years. Take another actual case: It is well known as a surgical principle that tissues of low organization, like ligaments and cartilage and the gums, when wounded, draw more largely in healing on the constitutional vitality of the patient than do the more highly organized tissues of the body. Ignorance of that principle resulted fatally in the case of a lady of a moderate degree of health and strength that required constant care, whose dental attendant extracted sixteen teeth at one sitting. On going home she took to her bed and died from vital exhaustion in a fortnight. Now, no doubt these operations were skillfully done, but the skill was misapplied; and you know the axiom: "The greater the skill misapplied the greater the blunder." Many less serious cases might be mentioned. Now, what I would urge, as from my observation for some years in our own specialty, is the greatest need of more and constant attention, in the schools and with practitioners, to what a zealous doctor, now deceased, used to call the "underlying principles as the basis of correct practice."

With a knowledge of those principles, and how to apply them, one need have no question in what domain he is properly working.

---

#### DISCUSSION.

Dr. William Carr asked Dr. Williams where he thought the fault lay for the lack of the preliminary knowledge needed as the basis of dental professional education.

Dr. Williams answered that it lay in the fact that the dental schools did not teach the principles of medicine and general surgery to the students, and did not impress the necessity of the application of these principles upon them. The highest ambition of many is to do skillful operations. Any jeweler could do these operations. Unless the dentist has a thorough knowledge of the fundamental principles of medicine and surgery, he will never be sure to practice his profession worthily. He related an instance of a pupil who was about to graduate from one of the schools in Boston, who showed by his questions that he was woefully ignorant of the plainest principles which govern the treatment of diseased teeth. Under the present system of teaching students are too much taught to do things by rote.

Dr. Carr said that the fault lay in the want of a rule insisting upon a preliminary fitness before a student was admitted to a dental school. In New York State before a student can be admitted to the study of law or medicine he must have a degree from some reputable institution of learning, either the bachelor of arts or master of arts, or at least a certificate of fitness from the regent of the university. He thought the day was not far distant when the dentist would be really as much a specialist of medicine as the oculist, when it would be required of him to first get the M. D. degree, and then his dental degree as a specialist. There is a movement on foot now to accomplish this result in New York.

Dr. Noble asked if they looked up the history of students before matriculation, to learn whether they were possessed of these qualifications.

Dr. Carr said they did not now, but they intended, or at least hoped, to have it so in the future. At present the preliminary examination is of the most trifling character. This thing will never be righted till we take it out of the hands of the colleges. It is too much of a temptation to the officers of a college when a young man says that he can not afford to study so as to pass a reasonable examination, and who promises to do his best during the course. He did not mean that the fee

was the temptation, but that the sympathies of the faculty were worked on. They make a mistake, for it would be better for the student to be held back for two years, if necessary, till he has had time, by study, to train his mind for the reception of the knowledge he must master in order to practice dentistry intelligently. The fault, too, often laid with the preceptors of the students or the dentist who is asked to advise the young man about the study of dentistry. In every case he insisted upon his students possessing a good general education preliminary to their going to a dental college.

Dr. Noble agreed that the preliminary examinations in the dental colleges were generally very trifling, and that every dentist should refuse to receive any student till he has fitted himself by study to enter the college.

Dr. Carr related an instance of a young man who, having failed entirely in the effort to go through the course in the dental college, set up an office, called it a dental association, and began the practice. Having been arrested for practicing illegally, he promised not to practice in the State if he was released. He was released and came to Dr. Carr and asked him what he was to do; said he could not go into any other kind of business, but could make a living if allowed to practice dentistry. Dr. Carr told him to go to the college. He said he could not, as he was on bad terms with the professors. He opened another office, was arrested, and fined \$100. He then applied to the college, but failed completely in his preliminary examination. This was in March. In October he passed the preliminary examination, got into the college, and in the course of five months passed the junior, senior, and final examinations, got his diploma, and is now practicing, and no one can hinder him. This is an example of how an ignorant fellow can get through the college without getting well grounded in the fundamental knowledge of medicine and surgery.

Dr. J. F. Thompson said it was gratifying to compare the dentists of to-day with those of forty years ago, and see how much higher is their present status, in comparison with their medical profession, than it was then. At that time the medical profession did not look upon dentists with much favor; now we meet as a section of the first Pan-American Medical Congress, and we must sustain ourselves on that high plane. We must educate our young men so that they will honor the profession, and the preliminary education is of the utmost importance. When we look around and find that almost every State has passed laws to protect the profession and the people from illegal practitioners, we realize that the profession of dentistry is one worthy of being a member of, and we should see that as far as we can control it, everyone shall be fit for the profession before he is allowed to enter it.

Dr. Fletcher was in accord with any movement intended to raise the standard of preliminary fitness for students. He said there was no excuse for anyone to try to enter the profession unless his mind had been so trained that he could reason and think of things in an abstract way. The mind was like the muscles of the body in its need of training before it could do any important work. He hoped the day would come when no student of a dental school would receive a diploma until he was examined by some board of undoubted qualification and disinterestedness, and his knowledge and fitness passed upon.

Dr. E. S. Talbot said that in the State of Illinois dental matters were in a bad way. Any man who wished to practice dentistry there could do so, and there was no one to prosecute him if he was not qualified. He spoke of the ease with which a dental college could be established in Chicago; said that some twenty-eight had already taken out charters. He did not know how many were now running, but thought six or eight. In some instances, the professors in these colleges are men who themselves never had a degree, but received them at the close of the course. The consequence is that no place in the world is so overrun with incompetent dentists as Chicago. He felt safe to say that over half his new patients for the

last five years were those who had their mouths mistreated by these incompetents. The legislature will not pass a satisfactory law, for the colleges do not want such a law. The thing to look forward to and to work for is to get a uniform law in every State. The laws passed by the States of Massachusetts, Minnesota, and New Jersey are good. A man going to any of these States to practice would have to pass an examination, and if he failed it would throw discredit on the institution from which he had graduated. If there were such a law in all the States it would enable us to regulate the colleges.

Dr. Carr said that three years ago students from two or three colleges had failed to pass the examination before the New York State board. Soon afterwards representatives from the faculties came to us and wanted to know just how high our standard was to be, so they would know what their students would have to be able to pass. It would soon bring a college into discredit if their students did not pass the examination of a fair and honorable State board of dental examiners.

Dr. Noble said that by the law of the District of Columbia a man who comes here to practice must have a diploma from a college that gives three full years of instruction.

Dr. Williams Donally said that he thought the only way to remedy the present evil of insufficient education among the dentists was for the profession, or some branch of the profession, to take hold of it. Probably the best way is by means of the State boards. Congress can not pass an interstate law regulating dentistry, but if we could get the State boards of the different States to work together the States might be got to do it. The colleges would see that their interests are favored by a strong law requiring a high educational qualification.

Dr. J. F. Thompson said the only way such a state of affairs as Dr. Talbot described as existing in Illinois could be remedied was by concerted action on the part of the best men in the profession. By this the status of dentistry could be placed on as high a plane there as in any other State. In Virginia they had an excellent law, which required an examination by the State board of everyone who desired to practice in the State, and the examination was of such a character that it made the students who had graduated from the colleges tremble when they returned to practice in Virginia. It took twenty-five years of effort to get this law passed, and he thought that the same effort would get the same result in Illinois.

Dr. W. H. Potter, of Boston, thought that the examining boards were not the best means to bring up the standard, but that the schools must do it. In Massachusetts the examining board is far more lax than the schools. The trouble is that the board is more or less influenced by politics. A good preliminary education is of the utmost importance. Without this foundation it is folly to expect a fine superstructure. The profession needs educated men; not only professionally educated, but generally educated.

Dr. Williams, in closing the discussion, said he was glad to have heard such a unanimous expression of the belief in the necessity of the preliminary examination. The knowledge of the principles of medicine and surgery was important for orists, but it was very discouraging for a teacher to try to get such knowledge into the head of a student who did not have a good preliminary knowledge and education. What should be exacted of the schools was the teaching of the principles of medicine and surgery, and impressing on the minds of the students the value of these principles in their application to the practice of oristry. Forty years or more ago it had been impossible for one to get an opportunity to study dentistry in a reputable office unless he agreed to take a full course of medicine. This, it seemed to him, was as it should be always.

## EVIDENCES OF PREHISTORIC DENTISTRY IN CENTRAL AMERICA.

By R. R. ANDREWS, A. M., D. D. S., of Cambridge, Mass.

MR. PRESIDENT AND GENTLEMEN: Perhaps one of the most interesting exhibitions of prehistoric dental work that the world has ever known may be seen within a few months in the Central American exhibit of the Peabody Museum, at Cambridge, the result of a recent exploring expedition at Copan, Honduras. This collection is being fast put in order and will soon be on exhibition. It seems particularly fitting that a brief description of this work should be given at this meeting, the dental section of the first Pan-American Medical Congress, showing, as it does, the skill of the workmen of Central America, who did the work over a thousand years ago. In the report of Mr. M. H. Seville, one of the explorers, it is stated that the party found forests growing over the site of their exploration, that workmen had to cut down these forests, and then the excavations began. A very large temple was unearthed, and near this the homes of the former occupants. Tombs were found under the floors of what appeared to be the living rooms, and it would seem that these tombs were built in the foundation, before the house was built, for the purpose of burying the dead. The contents of some of these tombs, with the exception of the curious small ornaments that were found within, consisted of only particles of the former skeleton and only the crowns of the teeth covered by enamel. All the rest had turned to dust from age. In some of them the teeth, roots and all, were fairly perfect. Many of these teeth were found to be filed on the cutting surface, from the center toward the mesial surface, forming a notch as though a shoulder had been cut in the teeth. And this was quite deep, running one-third up the length of the crown. This was found also in the lateral incisors and cuspids, but not in the bicuspid or molars. It would seem that the teeth of the men were filed in this way, while the women's teeth were filed in three points, deeply filed and beautifully polished. In the teeth of the men, as a mark of distinction, perhaps, a hole was drilled and a piece of green jade inlaid. This piece was circular and beautifully polished, and inlaid in the hole that had been drilled or bored in the front surface of the enamel. These inlays varied from one-eighth to three-eighths of an inch in diameter. In one of the teeth, the left upper canine, there was a circular piece bored out of the enamel, making a hole three-sixteenths of an inch in diameter and one-sixteenth of an inch in depth. It has no setting, but there are traces of a dark-red cement material still adhering to the sides of the hole, and this material may have been hardened and used as an ornament instead of jade. These teeth are all more or less covered with a deposit of tartar, showing that after taking all the trouble to ornament them they were apparently never cleaned.

In this collection of jade inlays there are perhaps a dozen in perfect condition, and although they were put in over a thousand years ago, and with the rudest implements, the work would be considered a credit to the most skillful workman to-day, with all the modern appliances for this kind of work. I carefully examined these specimens with a magnifying glass, and the fitting was very perfect. In most of these the cement had kept the setting in place in the most perfect manner. In two or three of them the piece of green jade was loose, so that it and the cavity in which it fitted could be carefully examined, and one could see how perfectly one fitted in the other, only a little film of some kind of a white cement separating the tooth. In no cases could I find any trace of decay around the inlays, although some of them had been in place a long time during life, as is clearly shown by a thin film of tartar covering the surface of the enamel. Is not this the first record of an inlay, having been placed there over a thousand years ago?

With the description of one other specimen, I have done. This is by all means the most interesting of all these specimens from Copan. It is a left lateral supe-

rior incisor, made from some kind of a fine, dark stone, taken with other teeth which had inlays from one of the skulls found in a grave there, and Mr. Seville, who found it, assures me that it was taken from the socket of the left superior lateral incisor, where it had been implanted for over a thousand years. There were no bands or anything of the kind to hold it in place, but that it had been in place and in use is clearly shown by a considerable deposition of tartar upon it. But for its color it would be a very fair representation of a lateral incisor tooth, the root being smooth and rounded like the root of a tooth. I have no doubt that this is the earliest case of implantation on record. The entire collection from this exploring expedition in Central America is one of very rare beauty, and it would well repay a visit to the Peabody Museum in Cambridge.

## THE DISCOVERY OF THE ANÆSTHETIC POWER OF ETHER.

By WILLIAM H. POTTER, D. M. D.

The progress of modern dentistry has been so rapid and its attainments so notable that there is danger that we, at least those of this generation, forget the important services rendered by those in our profession working nearly fifty years ago. A wonderful stimulus was given to surgery by the discovery of the anæsthetic power of ether in 1846. This discovery was made by a dentist, Dr. W. T. G. Morton, of Boston. Though others have claimed this discovery as their own, and have in many ways taken from Dr. Morton the honor due his most brilliant and useful work, there are few to-day who would deny his claim to having first established the fact that surgical anæsthesia could be produced and maintained by the use of sulphuric ether. In order to fully appreciate the honor which this discovery casts upon the dental profession it is well to review the circumstances under which it was made.

Fifty years ago the dental profession was largely occupied in furnishing good substitutes for the natural teeth. Vulcanite was not in use, and all dentures were mounted upon gold plates. On account of the pain accompanying the extraction of teeth, it was then the custom (at least in many cases) to leave roots in the mouth and fit plates over them. It was also the custom to use a very low-grade solder in attaching teeth to the plate. This solder, from its admixture of base metal, was unpleasant to the taste, and the method of fitting plates over remaining roots was uncleanly, and resulted in an ill-adjusted denture. In order to remedy these defects, Dr. Morton betook himself to careful study and experiment. He soon discovered the possibility of using a high-grade solder, and thus abolished the disagreeable effects connected with the solder heretofore in common use. But how to get rid of the roots which interfered with the fit of a plate was a question not so easily solved. It was Dr. Morton's experience that patients who had been accustomed to the insertion of plates without the removal of roots would not readily submit to their removal, even though it assured in the end a far more satisfactory result. It was the difficulty which Dr. Morton experienced in persuading his patients to submit to the pain of tooth extraction which incited him to find some way in which that pain could be abolished. His desire to perfect a process in mechanical dentistry, originated his efforts in behalf of anæsthesia. Doubtless, as time went on, the extended applicability of an anæsthetic agent was constantly before his mind. But it is interesting to note just what necessity started his inventive mind in courses destined to accomplish a widespread good.

Although complete surgical anæsthesia was unknown before Dr. Morton's discovery, a partial insensibility had in various ways been produced. The virtues of alcohol were known, and its power to diminish pain when given in extreme doses. Opium was often used in large quantities before a severe operation. Nitrous oxide

gas had been experimented with, but mainly in order to produce an interesting state of excitability. Hopes were entertained that it might be a reliable means of abolishing pain. Ether had for a long time been used by inhalation in cases of spasmodic asthma, chronic catarrh, whooping cough, and to relieve the effects produced by the accidental inhalation of chlorine gas. It had also been used, as had nitrous oxide gas, to produce exhilaration or intoxication. There was, however, no agent which could be relied upon even to greatly diminish the pain of surgical operations. Dr. Morton's zeal in the pursuit of anæsthesia soon led him to realize that he lacked the knowledge necessary for the investigation of a subject so intimately connected with medical science, and in order to fit himself for the work in hand he entered the Harvard medical school in the fall of 1844. It was in attendance upon the exercises of this school that he first met the men before whom he was destined soon to appear with his claim as the discoverer of surgical anæsthesia. In the wards of the Massachusetts General Hospital and at its operating theater Dr. Morton received renewed incentives for the work constantly in his mind. While the pain of dental operations needed relief, it was insignificant to that attending the operations of general surgery.

The history of Dr. Morton's experiments with ether is as follows: As early as July, 1844, at the suggestion of Dr. Charles T. Jackson, he used chloric ether locally to allay the pain of an aching tooth, and produced not only an alleviation of pain in the tooth, but a numbing of the surrounding parts. If ether could act locally as an anæsthetic, why could it not act generally and with profounder impressions? Such was the train of thought started in Dr. Morton's mind by the use of ether in the aching tooth. About this time Dr. Horace Wells, of Hartford, Conn., was experimenting with nitrous oxide gas, having become interested in its properties by the public exhibitions of Colton. In these exhibitions various stages of excitability and hallucination were produced which served to amuse a public audience. It occurred to Dr. Wells that nitrous oxide gas might be used to produce insensibility during tooth extraction. And he submitted to the influence of the gas while Dr. Riggs, of Hartford, Conn., extracted for him a tooth. The operation was declared to be without pain, and Dr. Wells believed that a new era in tooth extraction had arrived. His subsequent experiments, however, were unsatisfactory, and the idea of producing anæsthesia by nitrous oxide gas was abandoned for several years. But, though the experiments with nitrous oxide were unsatisfactory, yet they served to stimulate Dr. Morton in his efforts to produce a complete anæsthesia with ether.

His first experiments were with animals, a hen, a goldfish, and a pet spaniel having served as subjects. The effect of the drug was evident in these cases, a stupefaction and a certain degree of insensibility being produced. Dr. Morton also took ether himself, and produced a state of unconsciousness which seemed to offer immunity from pain. The best method of administering ether was an important question in Dr. Morton's mind, and a complicated apparatus, such as was used for nitrous oxide gas, was taken into consideration. In pursuing this detail of the subject, Dr. Morton sought the advice of his friends and acquaintances whose knowledge seemed likely to be of benefit. Among others he consulted his former instructor, Dr. Charles T. Jackson, a professor of chemistry in the Harvard medical school. Dr. Jackson gave him the benefit of his knowledge as to apparatus, and also gave him very valuable advice as to the necessity of using pure sulphuric ether, and as to where it could be obtained. On September 30, 1846, Dr. Morton administered ether to a patient in his office, and extracted a tooth without giving the slightest pain. The ether was administered on a handkerchief, and the result was so satisfactory that this operation can be considered as establishing the anæsthetic power of ether in a minor operation. In order to show the efficacy of ether in the full range of surgery, Dr. Morton applied to Dr. J. C. Warren, of the Massachusetts General Hospital, for permission to administer his

anæsthetic to a patient about to undergo a surgical operation. Dr. Warren entertained the proposition at once, and although not acquainted with the true nature of the anæsthetic, agreed to try to furnish an opportunity for putting it to proof. The readiness with which Dr. Warren granted the request of Dr. Morton is significant as showing that Dr. Morton had established for himself a reputation, not only in the profession, but as a student in the medical school. If this had not been the case, it is inconceivable that Dr. Warren should have so quickly lent his ear to a proposition which was at once bold and surrounded with danger.

The first surgical operation under ether was performed at the Massachusetts General Hospital by Dr. Warren, October 16, 1846. It consisted in the removal of a tumor from the underside of the lower jaw. The patient declared that he had experienced no pain, but only a sensation as if the part had been scraped with a blunt instrument. It was evidently a case of incomplete etherization, and this can not be wondered at when we consider the method of its administration. The inhaler consisted of a glass globe large enough to hold a fair-sized sponge. The globe had an opening at the top, through which the sponge was introduced and by which it was moistened with ether. To another opening at the side was attached a short tube which led to the patient's mouth. Subsequently a valve was introduced into the mouthpiece in order to regulate the supply of outside air.

Although the success of this notable etherization was not complete, it was still so pronounced as to convince all present that a useful discovery was at hand. No such removal of pain had ever before been accomplished. Though every sensation had not been removed, practical anæsthesia had been produced. But would ether suffice to prevent pain in a capital operation? This was a crucial test, and one which Dr. Morton was eager to try. It was not until the 7th of November, 1846, that an opportunity was given. On that day the thigh of Alice Mohan was amputated at the Massachusetts General Hospital without pain through the influence of ether, and its anæsthetic power was established to the complete satisfaction of the surgeons who witnessed the operation. A new era was thus ushered in by the advent of painless surgery.

It is not probable that the dental profession will ever again bring forth a discovery which will so advance the welfare of humanity as did Dr. Morton's. In his distinguished career several important points deserve attention. In the first place, it is to be noted that when Dr. Morton wished to make a decided advance in the dental profession he at once felt the need of a more thorough study of general medicine, and only by devoting himself heartily to its study was he able to arrive at the desired results; and to-day advance in our profession must be looked for along the same lines. We can not be true specialists without being thorough generalists, and in asserting that a thorough knowledge of medicine and surgery are necessary for a dentist, I do not mean a mere theoretical knowledge of these subjects. We should walk the hospitals and see the cases as did Dr. Morton. How else can we know what disease and its remedies really are? How else can we get the broad views which are necessary if we are to be wise and competent operators in the oral cavity? However much theoretical medicine the dental student of to-day may know, he does not know the cases as does the medical student. Is it not probable that one reason why Dr. Morton was so readily accorded the opportunity to test his new discovery in the Massachusetts General Hospital was his having been present there as a student? He was known by the surgeons as an earnest worker, and his efforts for the advancement of medical science were not despised. Because mere manipulative skill without a broad and thorough medical education can do so much in establishing a dental practice, there is danger that the profession will rest content with the training up of mere artisans, having just enough medical knowledge to save them from serious errors. It is from a union of broad medical education and

great manipulative skill that we are to expect notable advances in the dental profession. From constant work in the oral cavity the dentist acquires a mechanical skill which is beyond what the general surgeon can hope to attain in the same territory. Let thorough medical education be joined to the dentist's highly trained mechanical skill, and brilliant work can be looked for in many of the operations in the oral cavity which are now performed by the general surgeon. Our dental schools should have clinics for the practice of oral surgery, this to include not only operations on the teeth, but also on any and all the tissues in the oral cavity. I do not argue that every dentist should practice the full range of oral surgery, but I do claim that every dentist should have sufficient medical instruction to readily adopt the more enlarged sphere of action should his tastes and opportunity favor such work.

Another teaching from Dr. Morton's life is that mechanical dentistry should not be despised. His reputation was first gained as a maker of artificial plates and as a skillful adjuster of artificial vela and appliances for restoring impaired facial members. His skill in the latter direction gave him much reputation, inasmuch as the work was of a more unusual nature than that of making plates and required a greater degree of manipulative skill. Who would imagine that from a desire to perfect the details of an artificial plate experiments would be undertaken which would result in the complete removal of pain from surgical operations? Yet such was the case, and the dental laboratory must evermore be honored as the birthplace of an idea which ranks with the greatest discoveries of the age. Although Dr. Morton's claim as the discoverer of the anæsthetic power of ether is now quite generally allowed, there were times when rival claimants tried to take from him the honor which should have been his. Dr. Morton had little uninterrupted satisfaction or substantial profit to reward his work, but this was largely due to the mistake which he made when he decided to patent his discovery. Had the discovery at the first been given to the public, its reception by the medical profession would have been with much less suspicion and with much greater honor.

Such were the apparent profits to be realized from the discovery that the granting of a patent conveying exclusive right to the discoverer stirred up endless controversy as to originality and resulted in great financial loss. From this experience of Dr. Morton can be learned the final lesson of this paper. Whatever important inventions may originate in our minds, let us never take them to the Patent Office. Let it be the pride of our profession to give our best endeavors freely for the good of humanity, knowing that they will receive in the end a just reward.

---

#### DISCUSSION.

H. B. Noble said, while listening to the paper and remembering the inaugural address by Dr. Shepard before the Columbian Dental Congress, it occurred to him to wonder why two such papers, reviewing an old issue which he thought had been entirely and satisfactorily settled long ago, should have been written. He said that from a close personal acquaintance with Dr. Morton and the knowledge he had gained from his brother, Dr. Lester Noble, who was a student (and at present in the Massachusetts General Hospital) at the time Morton administered the ether for Dr. Warren's operation, and a good general knowledge of all that had been said and written upon the subject, he was convinced that while Morton deserved the credit of introducing ether anæsthesia into dental and surgical practice, his claim to having discovered its anæsthetic qualities was not founded upon the truth. The fact that he included Dr. Jackson with himself as a coinventor proved that he could not claim to be the sole inventor.

Dr. Potter said that the credit for the original invention of many very valuable ideas was and always would be in dispute, but he thought the undisputed fact that Morton made the use of ether known and introduced and pushed its use in dentistry and surgery entitled him to great credit. We know that ether had been made previous to his use of it, but it had never been used as an anæsthetic in surgical operations.

---

STATEMENT OF SOME FACTS IN REGARD TO THE ORIGIN OF THE  
PRACTICAL APPLICATION OF ANÆSTHESIA IN SURGERY.

By JACOB L. WILLIAMS, M. D., of Boston, Mass.

That sulphuric ether was repeatedly used as an anæsthetic by Dr. Long, of Athens, Ga., in his surgical practice about 1840, seems indisputable from the reliable evidence collected and published by the late Dr. Marion Sims, of New York, but a few years ago. The fact that Dr. Long did not publish its use to the world does not affect its priority. Next comes, about four or five years later, the experimental discovery and practical application, by Dr. Wells, of Hartford, Conn., of the anæsthetic effects of nitrous oxide gas. Then, some facts (known to me, as I was behind the scenes): About a year later Dr. Morton, remembering vaguely that Dr. Wells had faith in anæsthesia by inhalation of something, applied to Dr. Jackson, who informed him that from his (Dr. Jackson's) personal experience sulphuric ether had relieved his suffering from the accidental breathing of chlorine gas, adding a caution in regard to its use. Dr. Morton finding Dr. Jackson's information correct in regard to the "lethal" effects of sulphuric ether, by persuasion induced Dr. Jackson to unite with him in procuring a patent to control its use. Dr. Jackson's medical friends reminding him of the breach of ethics in getting such a patent, he withdrew from the patent. It was then that Dr. Morton claimed the sole discovery of ether anæsthesia, and wishing to have some respectable backing, he went to Dr. John C. Warren, the head of the surgical staff of the Massachusetts General Hospital, and said in his persuasive way that he had discovered a "compound," he called "letheon," that would prevent pains in surgical operations, and would be pleased to show its effect on some hospital patient. Dr. Warren consented to the trial, which proved successful, but he, with the rest of the staff, declined to indorse or adopt it unless they knew what it actually was. Of course Dr. Morton had to tell them that it was sulphuric ether. They then began its use, and it was their indorsement which gave it the successful start in the surgical world, without which it is very probable it might have fallen into the list of empirical fancies.

The summing up of these facts seems like this: Dr. Long's successful private practice, followed after several years by Dr. Wells's success, which his diffident nature hindered him from pushing to notoriety, then Dr. Jackson's information to Dr. Morton, which he, Morton, followed out and brought to the notice of the surgical staff of the Massachusetts General Hospital. These surgeons, having eliminated its elements of quackery, tried the substance effectually and with their substantial indorsement gave it to the world. To that indorsement, it surely seems, is due the permanent consideration that anæsthesia has since received.

---

DISCUSSION.

Dr. Taft said he had been personally acquainted with Morton, had seen him administer ether frequently, and usually successfully. Had also made himself familiar with all the literature of the subject, and that the statement of Drs. Williams and Donnally agreed with what was generally accepted as truth at the time.

## PRINCIPLES UNDERLYING THE REGULATION OF THE HUMAN TEETH.

Dr. E. A. BOGUE, of New York.

In the great majority of cases irregularities in the position of teeth arise from the dental arch being too small. The causes which produce this diminution of size are often obscure. We say heredity; we see the roots of pulpless deciduous teeth remaining too long in their places and deflecting the crowns of permanent teeth away from their proper positions. This deflection is generally, though not always, inward toward the center of the mouth. We guess that the failure to masticate properly may in some way, as yet unknown to us, produce these results, as we see them most frequently in those classes where the food is carefully prepared by cooking and made fine for eating. But be the causes what they may, the effects are certainly present, and the problem before us is so to correct irregularities in the position of the teeth as to produce the nearest approach to the normal arch which will, through its own perfections, remain where it is put. It is only through obedience to the laws governing the growth and development of the child that we can hope to obtain permanence in our results. What, then, are these laws, obedience to which means success and transgression failure? The first one to be borne in mind is that the child continues to grow up to 18 years of age or later, according to the age at which the wisdom teeth erupt. Eighteen is mentioned because that is the age at which the wisdom teeth generally appear, and yet several cases have lately come to my knowledge in which practitioners have advised the removal of the retaining fixtures which maintained an expanded arch before even the cuspid teeth were fully erupted, thus losing all that had been gained by months of previous effort. The second law is that the crowns of the permanent teeth that are packed away in the jaws of the child of 6 years of age, awaiting their time of eruption, are as large as they ever will be. A fact in connection with this law is that at this age these crowns have no roots. Another fact is that the central incisors lie outside of and anterior to the lateral incisors, while the cuspids which develop much later are almost alongside of the central incisors, being at the same time much higher up in the alveolus. As the roots develop the crowns push through the gum, and at this period a very slight obstacle is enough to deflect these crowns from the position which they should normally occupy into abnormal, or as we say, irregular positions. The normal development is of the lower central incisors first, the upper central incisors next, these latter often standing quite apart until the lateral incisors make their appearance, causing a slight approximation. At from 12 to 14 years of age the cuspids make their appearance, the lower ones some months, oftentimes a year, previous to the upper. These four cuspids, when fully grown, have the longest roots of any of the teeth and are the firmest in their positions; so firm, indeed, that if teeth posterior to them are extracted the remaining back teeth move forward toward the cuspids. If any of the four incisors are extracted the remaining incisors drop back toward the cuspids, but the cuspids remain more nearly stationary than any of the teeth in the mouth, and this through life. This is the third law that we need to bear in mind. It will perhaps be well in passing to recall the fact that the cuspid teeth are, in the lower animals, especially the carnivoræ, the prehensile teeth. Hence it was that they should be the strongest and firmest teeth in the mouth and the longest to endure; otherwise these animals could neither catch nor hold the prey upon which their existence depends. A fourth law to be borne in mind is that the lower molars incline inward toward the tongue, while the upper molars incline outward toward the cheek. The lower molars develop first, the upper molars afterwards, being directed in their course, if normally developed, by their contact with

the cusps of the lower molars. This results in the upper molars and bicuspid sitting astride of the outer row of cusps of the corresponding lower teeth. Ignorance or neglect of this law not infrequently has caused the extraction of a bicuspid or a molar during the period of development, the result of which is beautifully illustrated in two cases which I herewith present. In one of these cases the extraction of a lower bicuspid took place. In the other, non-development of the corresponding tooth on the other side of the mouth brought about practically the same result. It will be seen that the failure of the molars to properly interlock the cusps as they developed incapacitated the left side of the mouth, in the case of non-development, completely, so that the patient never masticated on that side, and the development of the facial muscles was hindered, irregularity of the lateral incisors was produced, and thus the left side of the face of an otherwise pretty woman was sufficiently unlike the right for her to apply for professional assistance, although at that time she was totally unaware of the cause of the defect or of the fact that mastication had never been performed on the defective side of the mouth. A sixth law is that the lower incisors normally lean forward, forming a low arch, with the cuspids acting as abutments, while the upper incisors, overlapping the lower, are drawn inward continually by the action of the upper lip and normally form their arch by resting against the outer edges of the lower incisors. Hence we see in the great majority of cases that the regularity of the upper incisors, which are so apparent, is controlled by the position of the lower incisors, which are generally scarcely visible, so that if the lower incisors and cuspids are regular, the upper ones are sure to be if they close outside the lower. This is true whether the upper teeth stand closely enough together to touch one another or not. This position is illustrated by the drawing of the jaws of a savage, which I herewith present, showing the upper incisors perfectly regular, notwithstanding the space existing between the lateral incisors and the cuspids.

Allow me, in closing, to recapitulate these six laws: (1) The child continues to grow up to 18 years, or the time for the development of the wisdom teeth. (2) The crowns of permanent teeth are as large in circumference at 6 years of age as they ever will be, and they are packed away in the alveolus with regular irregularity, the central incisors lying in front of the laterals and the cuspids almost over them. (3) The cuspids are the firmest and least movable of all the teeth in the mouth, so that all the other teeth incline toward them. (4) The lower molars incline inward and the upper molars outward. (5) Each class of lower teeth develops before the corresponding upper teeth, and thus guides, or ought to guide, the upper teeth into a right position. (6) The lower incisors normally lean forward to form an arch with the cuspids, and so support the arch of upper incisors, which, closing outside of the lower ones, are constantly drawn toward them by the action of the lips.

---

#### DISCUSSION.

Dr. E. S. Talbot said that when irregularities of the teeth were caused by the fact that the teeth were too large for the jaws the reason of the smallness of the jaws could generally be ascribed; first, to heredity, where the jaw seemed to be derived from one parent and the teeth from the other; second, to a neurotic temperament in one or the other of the parents. The child inherits this neurotic condition and, because of the faulty nutrition consequent upon it, at the age of 6 or 7 years the jaw ceases to grow. We all know that the brain does not increase in bulk much, if any, after this time, and in these cases the jaw ceases to grow at the same time. The third cause is constitutional disease in the child, such as scarlet or other fever. The interruption in nutrition caused by such sickness will cause the jawbones to cease growth. In regard to the teeth standing

inward, as shown in the illustration, this is because, while the lower jaw is developed normally, the development of the upper jaw was retarded by some cause and the teeth as they came through were crowded out of line. It is not true, as the paper says, that a man's growth is completed by the eighteenth year. Growth usually continues until the twenty-second and frequently till the twenty-sixth or twenty-seventh year, and in exceptional cases till as late as the thirty-sixth year. He spoke of the regulating systems of Drs. Farrar, Patrick, and Angle, condemning them because they used the molar teeth as anchorage to move the cuspids back to fill up the space made by extracting the first molar. He said that the cuspid has such a long root and is so firmly fixed that the posterior teeth will move forward instead of the cuspid backward. He described a case of a gentleman who was at the clinics in Chicago at the Columbian Dental Congress to have the cuspid and bicuspid implanted. Upon preparing for the operation the bicuspid was found unerupted and the implantation had to be abandoned. Subsequently an attempt had been made to move the anterior teeth, which were badly crowded and projected from their proper position, back to fill the vacant space and into their proper position. The molars were used as points of resistance, and the consequence of the force applied had been to move them quite inside the arch; so they did not touch the corresponding teeth in the upper jaw. This is an instance showing the futility of trying to move the cuspid by anchoring on the molars. The only sure way to accomplish the movement of these teeth is to use the back of the head for resistance.

Dr. William Carr asked Dr. Talbot if adenoid tumors, nasal polypi, and other growths which caused mouth breathing were the cause of irregularities in the teeth.

Dr. Talbot answered that these diseases came together and did not sustain the relation of cause and effect one to the other, except that anything which caused mouth breathing by bringing about the habitually open mouth would, by destroying the effect of support by the lower teeth upon the upper, allow the upper teeth and alveoli to grow down and the teeth to protrude.

Dr. M. H. Fletcher said that one fact usually left out of discussions on the cause of irregularities of the teeth is that bone will be absorbed by pressure of the teeth if force is applied to move it, thus removing the bone from in front of the tooth, and that will grow around it to hold it firmly in its new position. From this it follows that in cases of overcrowded teeth, if they are treated in time, the shape and size of the jaw can be corrected by bringing pressure to bear upon the teeth.

Dr. Carr asked Dr. Talbot if mastication had an effect upon the development and shape of the jaw and the regularity of the teeth.

Dr. Talbot said yes; that both the lower and upper jaw were developed by use and friction, and that if children were taught to masticate their food properly the jaws would be better developed.

Dr. J. Taft asked Dr. Talbot if he had said that the jaws were fully grown at the age of 6 or 7 years.

Dr. Talbot answered that he had said that in children who had inherited a neurotic temperament they were; not in the case of normally healthy children.

Dr. Taft spoke of the influence of properly masticating the food upon the growth of the jaws and the general health of the system. He insisted upon the great importance of teaching the parents of children the necessity of using the teeth. He said too much of the food given to children is prepared so as to give no exercise to the jaws, and that not only do irregularities and lessened development of the bones of the face occur in consequence of this, but the structure of the teeth is less dense than it would be if the children should use their teeth habitually in masticating hard substances. To teach people to use their teeth, and thus prevent irreg-

ularities, would be better service than to correct irregularities. This lack of properly masticating the food is much more general than is usually supposed, and should receive more attention. The teeth, as we know, do not all erupt at once, and if they are used those which are erupted will by reason of the shape of the cusps bring the latter ones into proper occlusion. This emphasizes the necessity of early teaching the facts in regard to properly masticating food.

Dr. S. B. Brown said that in his town, Fort Wayne, Ind., they had had a teacher who was so impressed with the fact that the jaws and teeth needed exercise to insure their well-being that he advised the parents to have the children eat parched corn.

Dr. Taft said that it was easy to see how the proper use would increase the size and strength of both jaws and the teeth. The act of masticating caused pressure which would expel the blood from the capillaries acted upon, new blood would flow in, carrying new material, which would enlarge and strengthen the parts. Thus the bones would be larger and stronger, the teeth more dense, and the gums firmer in structure and in their hold upon the teeth. He said that tobacco chewers usually had gums which extended well down upon the teeth, of good color and healthy. On account of the food they use the jaws of aborigines are usually broad and strong and the teeth large and good.

Dr. Finlay Hunt spoke of a report made by Dr. Winder of the result of the examination of about 1,000 crania of the Indians in the northwestern part of the United States. About one fourth of these skulls had lower jaws; thus they contained in all about 20,000 teeth. In all these there were less than 50 showing any trace of caries. In one cranium, belonging to a half-breed, however, there was decay in both upper and lower jaws. In Dr. Hunt's view, the preservation of the teeth depended upon the preservation of the whole physical system. Civilization, by cultivation of the mind and brain, tends to expand the upper head and contract the lower part. Disregard of the laws governing the development of the whole body was the cause of the lack of development of the jaws. At birth the maxillæ of a child are almost perfect semicircles; as the teeth erupt the jaws elongate; when there are 20 teeth the jaws are full. They extend clear back to the articulation of the jaw, and after this the jaw elongates enough to receive three more on each side of each jaw. The jaw is elongated and alveolus is formed to contain the whole 32 teeth of the complete denture. The constant pressure of the tongue upon the lower teeth tends to expand the lower jaw, and as these teeth are erupted first they have a controlling influence upon the upper teeth as they appear and regulate their position. All the muscles of the face which come into contact with the teeth tend to determine their position.

## HYGIENE OF THE MOUTH.

By CHARLES E. FRANCIS, D. D. S., M. D. S., of New York.

The specialty which we have chosen for our field of professional practice is one fraught with great responsibilities, demanding of its members a very considerable degree of intelligence, good judgment, skill, and faithful manipulation if its benefits to the human family are to be fully realized. Perhaps no other branch of medicine can reach and benefit mankind to a greater extent than the department of dentistry. The health, comfort, happiness, and length of life of members of all communities depend greatly upon the condition of their organs of mastication. If neglected, decayed, and broken they are unfit for the proper comminution of food for nourishing the animal tissues. Imperfectly prepared pabulum forced into the stomach overtaxes and irritates this much-abused receptacle, deranging its

function, causing indigestion and attendant evils to which so many human mortals are subjected. And furthermore, when the teeth become diseased and painful they wear heavily upon the nerve forces, cause loss of restful sleep, and unfit their unfortunate possessors for the duties of the day. They also taint the breath, corrupt oral secretions, impair speech, and often make life well nigh miserable. And where the dental arches are contracted, the teeth irregular and crowded out of proper position, the face is bereft of its natural rounded contour and the features become more or less distorted. This, together with surfaces of the teeth clouded with dark stains and loaded with offensive accumulations, are often a source of dire mortification to their possessors, and objects unsightly and repulsive to whoever beholds them.

To allay pain occasioned by a diseased condition of the calcific organs within the oral cavity and restore them as far as possible to a state of health and usefulness is one of the chief duties of the dental surgeon. To remove such as are beyond the power of restoration and are a source of continued irritation; to insert artificial substitutes for filling vacant spaces caused by these removals, constitutes also a large share of the dentist's occupation. For the performance of these manifold and often complicated duties the student of dentistry is trained and fitted in our excellent institutions for dental instruction. For the better fulfillment of these duties, and to keep alive and fresh all matters pertaining to practice, dental societies have been organized and are in active existence all over the country, where members of our specialty from time to time convene to consider and discuss all matters of professional interest. And every month in the year there comes to us our favorite journals exhibiting pages teeming with writings of earnest workers, who thus impart whatever new they have discovered or have gathered by experience, observation, or experiment; and so do the members of our fraternity endeavor to increase their usefulness and to render better service to communities that look to them for such attentions as they need. But however earnest may be the efforts of the dentist to benefit his patients in the way of repairing, restoring, or otherwise treating broken or diseased dentures, and however satisfactory may appear the immediate results of his manipulations, he can not be sure that his excellent skilled labor will withstand the encroachments of time or his fond hopes for the durability of his operations be fully realized.

Diseases of the teeth and gums are, as a rule, due to habitual carelessness or a neglect to give them such attention as they need. Everybody must or should know that decalcification of the lime salts in the tooth structure is caused by a chemical action of acidulated accumulations remaining too long in contact with the teeth, and that diseases of the gums are, as a rule, occasioned by collections of food and salivary calculus, which are permitted to gather about their cervical borders and fill the dental interstices. The mucous membrane, from this unwelcome intrusion, becomes irritated and naturally recedes. Collections of calculus follow and become attached to the denuded surfaces; the alveolar territory is invaded and absorption induced, and where any idiopathic tendency to socket disease exists this disagreeable malady is sure to be developed.

According to the old aphorism, that "like causes produce like results," conditions within the buccal cavity which are productive of mischief, if allowed to continue or afterwards exist, are almost certain to witness a reproduction of similar forms of mischief. If, then, our patients expect to be permanently benefited by operations on their teeth, it is essential that they do their part in efforts to make them lasting. As "prevention is better than cure," the theory of prevention is a matter worthy their earnest consideration. In order to secure good dentures care is requisite at an early period of life. The deciduous teeth should be retained in the mouth and kept in a healthy condition until supplanted by their more durable successors, extraction being resorted to only in cases of extreme necessity.

Premature loss of the deciduous teeth means not only a loss of their useful services, but in a measure it interrupts or checks the full or perfect development of the dental arches. The permanent teeth also need frequent examination during the period of their eruption and to be kept free from stains or extraneous collections. Any suggestion of caries or decalcification should receive immediate attention, and all suspicious points be examined with the utmost care. Finely pointed searching instruments and magnifying glasses are essential for this purpose, and waxed floss silk passed between the teeth will also aid in disclosing defects. Cases of irregularity should invariably be corrected, certainly as much so as possible, in order that well-formed arches and perfect articulations may be secured; and when in regular order the daily task of cleansing them is much less difficult.

It has been said that "cleanliness is next to Godliness," and nowhere can this excellent law be observed to greater advantage than within the precincts of the oral cavity. Our patients should be made to understand the importance of giving due consideration to their organs of mastication, and instructions or advice on the part of the dentist impressively imparted. Our patients should also know the advantages they gain by having their teeth examined at frequent intervals—at least twice a year. I have reason to believe that many of our fraternity are remiss in this matter, and even where they give advice or warning their words are not sufficiently emphatic or comprehensive to become effective. People should be taught the use of a toothbrush and how to manipulate it to the best advantage, and the proper time for using it. They should also be instructed regarding the use of floss silk, toothpicks, dentifrices, etc., and the benefits to be derived from frequent and thorough rinsings of the mouth with water. Antiseptic mouth washes have also their benefits, especially where the gums are congested and receding from the teeth. The disgusting disease known as "*pyorrhœa alveolaris*" may often be held in check, and perhaps prevented, if proper attention is given in the way of keeping the teeth in good condition.

To the dentist who does all in his power to perfect his operations, it is certainly disheartening when at some subsequent period he discovers that his labors have availed but little. The best impacted fillings, if constantly menaced by agents of decalcification, are likely to become undermined and prove valueless. The dentist may cleanse the teeth of his patient with the greatest degree of thoroughness, treat diseased gums and alveolar borders until restored to health, and dismiss the patient with the feeling that the teeth of the latter are in perfect order, yet what material benefit may be expected if they are again permitted to become neglected and coated with vicious accumulations? It is a lamentable fact that so many individuals are habitually and inexcusably careless in this respect. Comparatively few give them such attention as they need, and many give them little or no care whatever, and perhaps never visit a dentist until some unbearable pain drives them thither for relief. Even then some of them seem to entertain the idea that their half-ruined dentures can be made almost as perfect as ever, and so insured from giving annoyance for all future time without further care or trouble on their part. So far as the dentist is concerned, he can never be too thorough in his examinations or in his operations of cleansing. Either is quite essential. Nor can the dentist be too particular in imparting hygienic instructions to his patients. Anticipation, or timely attention, and prevention constitute strong points in securing the preservation of the natural teeth.

## DEVELOPMENT OF THE VAULT; HISTORY OF DEFORMED VAULTS.

By EUGENE S. TALBOT, M. D., D. D. S., of Chicago, Ill.

It is a singular fact that depressed palates and irregularities of the teeth were first observed and described by medical men. Langdon Down called the attention of the medical profession to the fact that high vaults, as well as irregular-shaped jaws, were very common among idiots and congenital imbeciles. In a paper read before the Odontological Society of Great Britain he says, among other things, speaking of idiots in the Earlswood Asylum:

Of the most significant value, however, is the condition of the palate. I have made a very large number of careful measurements of the mouths of the congenitally feeble-minded and of intelligent persons of the same age, with the result of indicating, with some few exceptions, a markedly diminished width between the posterior bicuspid of the two sides. One result, or rather one accompaniment of this narrowing, is the inordinate vaulting of the palate. The palate assumes a roof-like form. The vaulting is not simply apparent from the approximation of the two sides; it is absolute, the line of juncture between the palatal bone occupying a higher plane. Often there is an antero-posterior sulcus corresponding to the line of approximation of the two bones. An appeal to the condition of the mouth is an important aid in determining whether the lesion on which the mental weakness depends is of intra-uterine or post-uterine origin. In the event of the mouth being abnormal it indicates a congenital origin, while if the mouth is well formed and the teeth are in a healthy condition it would lead to the opinion that the calamity had occurred subsequently to embryonic life.

Indeed, he went so far as to state that these conditions when observed in young children were pathognomonic of idiocy. Upon further observation, however, it was found that many idiots and feeble-minded individuals possessed low, narrow vaults. It was also observed that many sane persons possessed high vaults and v and saddle shaped arches. My own studies prior to the year 1887 not only show high and contracted arches among sane individuals as well as idiots, but that they are also very frequently observed among the deaf, dumb, blind, insane, criminals, drunkards, extreme tobacco users, extreme egotists, in neurotics and degenerates generally. It will be noticed, therefore, that no particular class of individuals is exempt from these deformities. The frequency with which they are observed in each class will be studied later. The fact that the high vault and contracted arch are not confined to any one class of individuals would prove conclusively that the high vault is not due to mental weakness. Dr. Clay Shaw (*Journal of Mental Science*, July, 1876) made extensive observations and accurate measurements of the mouths of idiots, and decided that "there is no necessary connection between a high palate and the degree of mental capacity of the individual." These deformities are never observed in connection with the first set of teeth. (I shall show later that they always form between the eighth and twelfth year.) The fact that they are developed in utero, or are of congenital origin, or a forerunner of idiocy, as advanced by Dr. Down, is entirely out of the question. Dr. Clay Shaw believed that a high palate is invariably associated with narrow pterygoid width and a narrow skull; but this theory is of little value. By a close examination of the vaults of the dolichocephalic heads it will be seen that such is not the case, but that they are also to be seen among the brachycephalic and mesocephalic heads.

## DESCRIPTION OF THE VAULT.

The roof of the mouth has received different names from different authors. One speaks of it as the arch, another the dome, still a third the palate. The word arch, although used in its proper place, is so often liable to be confounded with the dental arch that one is apt to become confused. Thus we frequently read of the v or saddle shaped arch, and we are quite unable to decide whether the writer intended

to refer to the dental arch or the roof of the mouth. The author has in former papers used the term vault to distinguish it from the dental arch, and we shall therefore continue its use in the present paper. The vault of the mouth is made up of the hard palate, the soft palate, and the alveolar process. The hard palate consists of two horizontal plates of bone extending from the superior maxillary bone upon either side and uniting at the median line, and from the anterior alveolar process in front it extends back on an average of 2 inches, when it unites with the soft palate. The hard palate is composed of six distinct parts, two incisive bones, two palate plates of the superior maxillæ, and two horizontal plates of the palate bones. The incisive bones, however, become so firmly united to the maxillary plate of bone so early in life that the suture becomes obliterated. The period of ossification of the median suture varies in different individuals, sometimes as early as the third and fourth years, and again as late as the fifteenth and sixteenth years. The author, in widening the arch by means of a jackscrew, has opened the suture of the median line in 14 different cases in children from 12 to 16 years of age. This was accomplished by very little pressure, showing that union had not taken place. As a whole, the hard palate may be described as a horizontal partition or floor separating the nasal cavity from the mouth. The anterior part of the palate bone unites and becomes a part of the alveolar process. The upper surface of the hard palate joins the floor of the nasal passages, which are divided in the center by the union of the vomer. This bone, which is quite thin at its middle portion and cartilaginous at the anterior part, begins to thicken as it reaches the floor of the nose, at which place it gradually produces a smooth appearance, dividing the nostril into two rounded arches. Upon the palatal surface it is very uneven. Along the median line we frequently find a rough ridge of bone resembling a section of rope, running its entire length, about the size of a slate pencil. Such a condition is frequently observed in Peruvian skulls. Out of 228 examined at the Peabody Museum, Harvard College, 16 had this peculiar appearance. In more modern skulls we find knots or rough lumps of bone at intervals along the suture. Again, we will observe a thick band of bone, from 0.25 to 0.50 of an inch in width, extending part way or the entire length of the suture. This thickness or prominence commences at the alveolar border, and becomes the widest at the second bicuspid and first permanent molar, where it gradually narrows to a mere point at a line drawn across the vault at the posterior surface of the second molar. The hard palate varies in thickness in different localities and differs in thickness in different individuals. Around the edge, where it unites with the maxillary bone and alveolar process, it is quite thick, and also at the median line, while about midway between these two parts the bone is as thin as tissue paper. I have also observed it from 0.12 to 0.18 of an inch in thickness. At the median line and just back of the incisors we find a fossa, which transmits the anterior palatine vessels and the naso-palatine nerves. At the posterior surface, upon either side, is a groove and an opening for the transmittance of the posterior palatine vessels and nerves. Both the upper and lower surfaces of the hard palate are covered with mucous membrane, which extends backward and unites to form the soft palate. Between the two folds of mucous membrane are muscular fibers for the purpose of moving the soft palate in different directions. The shape and length of the soft palate depend upon the distance between the œsophagus and the edge of the hard palate. If the head of the individual is dolichocephalic, or long, the soft palate will curve slowly backward, thus producing quite a long space between the incisor teeth and the uvula. On the other hand, if the person possesses a brachycephalic, or short head, the soft palate will curve abruptly, thus allowing only a short distance in the vault of the mouth. I have observed mouths where the head was so short from front to back that the soft palate descended nearly straight down without the slightest curve.

The alveolar process has already been described. The above description of the anatomy of the vault is quite sufficient for the purpose of the student. Should he require further details, refer to the standard text-books. The vault, taken as a whole, presents different shapes in different individuals.

#### NORMAL DEVELOPMENT OF THE ROOF OF THE VAULT.

If we examine the mouth of a child at the fourth or fifth year we find a well-developed jaw. The curves are all graceful in outline, and the contour of the dental arch is well formed. This could hardly be otherwise, for the reason that the jaw is growing rapidly for the purpose of accommodating the permanent teeth, and the circle of the alveolar process is larger than that of the teeth. Spaces exist between the teeth, and therefore crowding can not take place. We could not expect to find two vaults alike in height, width, or contour, although each is normal in itself. In the development of the jaws we have two structures, the hard, dense bone of the maxilla and hard palate, and the soft, spongy bone, the alveolar process. The maxillary bones develop and unite at the median line. The contour of the top of the vault is now established. It is held in position on the sides by the walls of the antrum, supported by the malar process and by the anterior alveolar process and maxillary bone. In this manner the vault is held in its natural position. The maxillary bones, like all the other bones of the head, develop in every direction in a general way until the growth is established. Between the ages of 4, when all the temporary teeth are in place, and 12 and 14 years, when all the permanent teeth are in position, great changes take place in the shape of the jaw.

In the face of a girl 3 years of age all the bones, together with those of the cranium, are undeveloped. The bridge of the nose is sunken, the upper lip is short, as well as the distance from the lower lip to the chin. In same girl at 13, while the width from cheek to cheek has not changed to any great extent, the length of the face from the chin to the top of the head is very marked. No part of the face has changed more than the lower part from the nose down. This change is due partly to the change in the angle of the lower jaw and partly to the development downward of the superior alveolar process. In young life the lower jaw presents an obtuse angle; this gradually changes, until at middle life it assumes a right angle. In order that the alveolar process and teeth may compensate for this change as the second set comes into position, the alveolar process lengthens with the eruption of the teeth. This is proved by the location of the mental foramen, which is situated at the superior border of the lower jaw early in life, and at middle life just midway between the upper and lower border of the bone. The same changes take place in the upper jaw. This is quite noticeable on the sides of the alveolar process at the roots of the first permanent molar soon after it has erupted. Upon examination we shall observe what seems to be a depression, but by careful examination we find that it is a lengthening of the alveolar process. When the crowns of the bicuspid are ready to advance and absorption of the roots of the temporary molars takes place, there is some irritation in the alveolar process. The first permanent molar coming into position advances farther than the line of articulation of the temporary molars, and the pressure of the jaws rests upon the first permanent molars. This fact, together with the irritation already mentioned, has a tendency to lengthen the alveolar process, so that when the bicuspid come into place there is a difference in the height of the vault. There are plenty of illustrations to show this development of the alveolar process, and every practitioner of dentistry has observed it.

One of the most common illustrations is that when the molar teeth upon the lower jaw have been extracted the molars upon the upper jaw (for want of an antagonist) drop down by the lengthening of the alveolar process. In this manner we obtain the difference in the length of the face. In those cases where the vault is very high the alveolar process is always very long and thin.

The depth of vault is also governed by the angle of the jaw. Thus, if from inherited constitutional disease, such as consumption, syphilis, etc., arrest of development of the maxillæ should ensue, the angle would not change from an obtuse to a right angle. It will be noticed that when the mouth is opened the anterior part has to travel a greater distance than the posterior part, hence either the anterior inferior alveolar process will elongate so that the lower incisor will articulate with the upper, or the anterior superior alveolar process will elongate to meet the lower incisor and bicuspid. Occasionally this will take place in both jaws. In either case the superior alveolar process becomes long and thin and the vault is quite high. In cases of arrest of development of the bones of the nose and when adenoid growths renders it impossible for the child to breathe through the nose; mouth breathing becomes a necessity, the jaws are separated, and the teeth not having a resting place the alveolar process elongates and a high vault is almost always noticed. This is the reason why imbeciles and all degenerates who keep the mouth open, as a rule, have high vaults. On the other hand, we occasionally notice the jaws brought closely together. This is due (1) to short rami; (2) to right angles of the rami to the body of the jaw; (3) to arrest of development of the alveolar process, and (4) to teeth with short crowns or teeth not fully erupted. In such cases the vault is low, the alveolar process thick, and usually the lower jaw is quite broad; the lips pout, the face is short and broad. Frequently the upper jaw is arrested in its development; the muscles of mastication are very set and rigid. The height of the vault, then, is not due to the roof's being pushed or pulled up by a pressure exerted through the vomer by the development of the sphenoid bone, nor does the shape of the base of the skull in any way affect it, as I have already explained. The height is due entirely to a growth downward of the alveolar process and teeth. The extent of the development of the alveolar process depends upon nature's becoming satisfied with her architectural figures, and harmonizing the jaws, alveolar process, and length of teeth. That the distance in height is changed from a child to a person of middle life is demonstrated by the following figures: Thus in 317 children under 5 years of age, before the development of the first permanent molar and alveolar process, the lowest vault measured 0.17, the highest 0.62, with an average of 0.42. If now we notice the height of vaults in children at different ages, we find, with two exceptions, a gradual advance in the height of the vaults, until in 4,614 adult vaults we have lowest 0.21, highest 0.84, with an average of 0.58. It will therefore be observed that the height of vault develops about 0.33 to 0.25 in depth after the permanent teeth commence to erupt. In 908 measurements of the vaults of ancient and modern Romans, Peruvians, Sandwich Islanders, Mound Builders, American Indians, Negroes, etc., the minimum height of vault was 0.25, while the maximum height was 0.88; average 0.53. By comparing these figures with those obtained from the examination of modern individuals, the lowest vault of the ancients is a little higher (0.04) than of the moderns, and the highest a little higher (0.04). The average, however, is a little lower than in the modern vaults of 0.05, thus showing that the ancient and pure races of individuals possess more uniform and lower vaults than modern. We would conclude, therefore, that the height of the vault depends upon the length of the face from the chin to the top of the head. So far as the height of the vault is concerned, no race, type, sect, or intellect can lay claim to high, medium, or low vaults. They permeate through all classes of individuals.

#### NORMAL VAULT.

What constitutes a normal vault would be a difficult question to answer. I possess six skulls, obtained under difficulties from a medical college, and not selected for any particular purpose. The lateral measurement was made between the roots of the second bicuspid and the antero-posterior measurement from

between the central incisors to the posterior border of the palate bone at a point intersecting a vertical line dropped from the posterior nasal spine. The height of vault was measured along a horizontal line extending from the alveolar process on one side to the alveolar process on the opposite side just back of the second bicuspid teeth. The following are the figures :

|            | Lateral.              | Antero-posterior.     | Height of vault.      |
|------------|-----------------------|-----------------------|-----------------------|
|            | <i>In.</i> <i>mm.</i> | <i>In.</i> <i>mm.</i> | <i>In.</i> <i>mm.</i> |
| No. 1..... | 1.31 = 33.22          | 2    = 50.80          | 0.37 = 9.42           |
| No. 2..... | 1.25 = 31.75          | 2.12 = 53.84          | .62 = 15.74           |
| No. 3..... | 1.37 = 34.79          | 2    = 50.80          | .43 = 10.92           |
| No. 4..... | 1.56 = 39.51          | 2.37 = 60.17          | .75 = 19.05           |
| No. 5..... | 1.62 = 41.12          | 2.25 = 57.15          | .50 = 15.24           |
| No. 6..... | 1.25 = 31.75          | 2.12 = 53.84          | .31 = 7.87            |

Nos. 1 and 5 possess very much the same contour of the dental arch, while Nos. 4 and 6 are very broad, with square dental arches. The heights of the vaults are all different, although two are flat, while the others are more or less rounding. If I were to hand you any one of these skulls and ask if it was a normal vault, you would most likely answer, yes. Yet all are normal as I view them, while no two are alike. I have examined hundreds of plaster casts where the teeth were all in a fairly normal position with similar results. Of 372 skulls of Peruvians, California Indians, Mound Builders, and American Indians, the lateral measurement varied from 1.12 to 1.75, and the antero-posterior from 1.75 to 2.75, while the height of the vault varied from 0.24 to 0.75. Oakley Cole made careful measurement of a number of skulls, chiefly in the museum of the College of Surgeons, London, England. The skulls examined fall into two series, viz., those of European origin and those of mixed races, and the results were as follows :

|                      | Num-ber. | Average length. |            |            | Average width. |            |            | Height.    |            |            |
|----------------------|----------|-----------------|------------|------------|----------------|------------|------------|------------|------------|------------|
|                      |          | Maxi-mum.       | Mini-mum.  | Aver-age.  | Maxi-mum.      | Mini-mum.  | Aver-age.  | Maxi-mum.  | Mini-mum.  | Aver-age.  |
|                      |          | <i>mm.</i>      | <i>mm.</i> | <i>mm.</i> | <i>mm.</i>     | <i>mm.</i> | <i>mm.</i> | <i>mm.</i> | <i>mm.</i> | <i>mm.</i> |
| European skulls..... | 34       | 58              | 40         | 49         | 42             | 31         | *35        | 15         | 5.5        | *9         |
| Mixed skulls.....    | 32       | 65              | 43         | 54.9       | 40             | 29         | *35        | 18         | 6          | *12        |

\* Taken at second bicuspid.

In each of the cases that I have examined, the dental arch was in a normal condition. I have also examined the skulls mentioned by Oakley Coles, and I have been unable to find a contracted arch in any of them. If, therefore, in the examination of thousands of skulls having normal dental arches, no two vaults are found to correspond, we must conclude that a normal vault is one where the dental arch is regular and the different outlines possess graceful curves, regardless of height, width, and length.

BY WHAT STANDARD SHALL WE MEASURE THE VAULT?

The width of the vault depends upon two factors ; first, upon the development of the jawbone proper; and second, upon the development of the alveolar process. Narrow jaws are rarely observed among the early races or modern pure races. In the examination of the thousands of skulls of early races in the museums of Europe and this country very few, if any, contracted vaults are found. This is also true of people who lead a quiet life, as illustrated in modern pure races. If the brain is in a healthy condition and the child properly nourished the jawbone will develop in size sufficient to accommodate all the teeth when they erupt.

The teeth will crowd against each other as they come into place, and a normal width of arch will be produced. If the brain is defective, as a result of some of the constitutional diseases and the jaw should become arrested in its development just before sufficient room had been secured for the teeth, they will crowd against each other, the arch will become broken, and the V or saddle arch, or some of their modifications, will be formed, hence a narrow, contracted vault. The amount of contraction depends upon the size of the jawbone proper; if the bone has become arrested early, the jaw being small, the contraction is usually very great. The alveolar process depends entirely upon the location of the teeth for its shape and size. Occasionally the teeth, which are small, are inherited from one parent, and the jawbone proper, which is large, from the other parent. In such cases the alveolar process will contract until all the teeth antagonize, when a small arch will be produced.

It has already been shown that the V and saddle shape arches and their modifications are observed as often among low vaults as among high ones, just as we have seen high and low vaults in normal jaws. The contraction is due to arrest of development of the jaw at the time of the eruption of the permanent teeth; the vault may be high or low. What appears to be a high vault is not in the height of the vault, but in the width. Having now explained the true cause of what appears to be a high vault, if we will refer to Clouston's classification we will find what he calls neurotic and deformed are both one and the same. Both are neurotic, but one is more contracted than the other. Both are due to arrest of development of the maxillary bones. In summing up our observation, we find that there are high and low vaults among the ignorant as well as the intellectual, among the colored as the white, among the brachycephalic and mesocephalic as the dolichocephalic, among the deformed or contracted as the normal. The width of vault depends upon the development of the maxillary bones; if they develop to a size sufficient to accommodate all the permanent teeth, there will be a normal vault regardless of height. On the other hand, if arrest of development of the jaw takes place these deformities result in a V or saddle arch or some of its modifications. How then shall we classify vaults? In the measurement of the height of vaults of 8,654 ancient and modern skulls in this country and Europe the highest was 0.88, the lowest 0.25, with an average 0.53. In the measurement of 6,387 mouths of living people over 20 years of age, the highest is 0.84, the lowest 0.21, with an average of 0.58. In the measurement of 616 insane people at the Eastern Illinois Insane Asylum, the highest is 1; lowest, 0.12, with an average of 0.54. Taking these figures into consideration, it is safe to average the height at 0.55. Allowing 0.15 an inch in each direction, we can call vaults which measure below 0.40 low vaults; those between 0.40 and 0.70, medium vaults; those above 0.70, high vaults. We could still classify those below 0.25 very low vaults, and those above 0.85 very high vaults.

The width of vault between second bicusps in 8,654 ancient and modern skulls, maximum, 1.63; minimum, 1.13; average, 1.36. In 6,387 mouths of living people, over 20 years of age, maximum, 1.50; minimum, 0.93; average, 1.19. In 616 insane people, maximum, 1.87; minimum, 0.75; average, 1.16.

The vast difference between the ancient and modern skulls of this country and Europe and those of living individuals shows conclusively that the jaws are diminishing in size. We must therefore arrange a standard by which we are to compare the width of the vault as we find them to-day, excluding measurements of ancient and modern skulls. Taking the 1.19 as the average width of vault, we will say that any jaw below 1.10 is a narrow jaw; one between 1.10 and 1.40, medium width; and one which measures above 1.40, a wide jaw.

## DISCUSSION.

Dr. M. H. Fletcher said that he considered the work that Dr. Talbot was engaged in as not second in importance to that of any scientific man in the United States, and that it was a real factor in the elevation of the profession.

Dr. J. L. Williams was glad to have heard Dr. Talbot's paper, and thoroughly approved the scientifically correct basis upon which he built up his conclusions.

Dr. Florentine Aguilar said there was great medico-legal importance in the studies prosecuted by Dr. Talbot, and it would be necessary to determine whether a high vault was or was not indicative of a disordered brain. He related a case which occurred some years since in Madrid. A priest who murdered the Bishop of Madrid was saved from death by his lawyer proving him insane, and it was brought out at the trial that a very high vault was a proof or an indication of insanity.

Dr. Daniel Guiterrez said that he had examined the mouths of many of the civilized Indians in South America. He found that they had unusually flat roofs to their mouths and good teeth, pyorrhœa alveolaris is unknown among them, and they are very rarely any of them insane.

---

THE RELATIONS OF SYPHILIS TO DENTISTRY.

By G. FRANK LYDSTON, M.D., of Chicago, Ill.,

*Professor of the Surgical Diseases of the Genito-Urinary Organs and Syphilology in the Chicago College of Physicians and Surgeons; Attending Surgeon Cook County Hospital, etc.*

It is not my intention to endeavor to present the comprehensive subject indicated by the title of my paper in all of its bearings upon the practice of dentistry. An entire book might be written upon this subject, and yet without doing it full justice. I will confine myself almost exclusively to generalities, but to such generalities as have a practical clinical bearing upon everyday dental practice. I will classify my subject as (I) the specific relation of syphilis to dentistry; (II) the nutritional relation of syphilis to dentistry. By the term specific I mean the relation of infectious secretion-bearing lesions about the mouth to dentistry. The second class embraces those disturbances of the teeth and jaws which are the result, not of the action of infectious syphilitic processes in loco, but of secondary nutritional aberrations incidental to the impression of syphilis directly upon the parts affected and indirectly upon these parts through the medium of the nerves and vascular supply.

I. It has appeared to me that the average dentist is inclined to overlook the possibilities of danger of transmitting syphilis to a healthy person through the medium of dental instruments and manipulations. A clean instrument from the standpoint of the dentist is not always a clean instrument from the standpoint of the surgeon. There are many men who consider that washing and wiping of instruments before and after manipulations about the mouth are all sufficient to prevent the possibility of the conveyance of infection.

I would at this juncture impress upon the dental profession the facts: (1) That an apparently healthy mouth may contain the poison-bearing secretion of syphilis. (2) That nothing short of the application of extreme heat, dry or moist, or the application of pure carbolic acid will make instruments surgically clean. It is by no means infrequent in my experience that syphilitic patients will submit themselves to dental manipulations without informing the dentist of their constitutional infection. In such patients an innocent so-called aphthous ulcer or "canker sore," as they are very frequently termed by the laity and by a certain class of

physicians, may be a poison-bearing syphilitic lesion. Operators who are brought in contact with the more aristocratic class of patients are rather loth to attribute lesions of the mucous membranes to syphilis, especially when such lesions resemble those innocent aphthous ulcers that frequently result from simple local irritation or from digestive disturbance. It is to be remembered also that a small mucous patch, syphilitic erosion or ulceration, or perhaps a small fissure, may exist at the bottom of some fold or reduplication of the mucous membrane and be overlooked, the mouth appearing on a superficial examination quite healthy. The poison-bearing lesion may appear and disappear very rapidly, yet the saliva and mucous secretion of the mouth may be none the less contaminated and remain so for some days after the complete disappearance of the lesion. It is by no means unusual for small syphilitic ulcerations to exist in the irregularities of the tonsils or folds of the fauces. A frequent location is between the pillars of the fauces, where only careful inspection can detect them. A superficial examination of the mouth and throat under such circumstances will disclose an apparently healthy oro-pharyngeal cavity. A small syphilitic ulcer or mucous patch may exist beneath the tongue or on the floor of the mouth, where it is concealed from ordinary inspection. Mucous patches far back upon the base of the tongue are frequently overlooked.

From what has been said, it is evident that from the standpoint of the possibility of infection, no mouth should be considered free from suspicion, and only by such suspicion can the dentist protect himself from the danger of infection of innocent patients. Several cases have come under my observation in which, while it would be difficult to positively prove that infection resulted from dental manipulations, my conscientious opinion is that infection resulted in this manner. I would warn the dentist particularly against the innocent-looking fissures and erosions of the lips and tongue which the patient usually fondly terms "cold sores." A benign-appearing fissure at the angle of the mouth may contain the contagium of syphilis. Oftentimes the patient himself is unconscious of the existence of syphilis in his or her system, but this innocence on the part of the patient is no safeguard against the infection of healthy persons. A very frequent lesion seen in the mouths of syphilitic patients is a superficial thickening of the mucous membrane, producing the so-called "milk spots." Here we have a pearly-gray infiltration of the mucous membrane with the syphilitic neoplasm, the secretion of which is highly infectious. I might remark that the secretions of the lesions of the mouth seen in secondary syphilis are the most infectious of all the manifold lesions of this disease, not even excepting a primary chancre. The frequency of the primary lesion of syphilis about the mouth is very much greater than is usually supposed. I have seen some thirty-odd cases of this kind. I have seen several cases in which patients presented themselves to me for diagnosis and treatment of primary syphilitic lesions of the tongue and lips, having been, at the time of my inspection, under the care of a dentist. The inference as to the danger of infection of healthy patients is at once obvious.

The safeguard of the dentist is: (1) To regard all lesions of the mucous membranes of the mouth, tongue, and throat as possible elements of danger of infection, no matter how innocent looking the lesions may be; (2) to remember that the healthiest appearing mouth may possibly contain in some obscure situation the poison-bearing syphilitic lesion; (3) that the secretions of lesions upon the mucous membrane in this location, certain tertiary lesions possibly excepted, invariably contain the contagium of syphilis in a highly active and virulent form; (4) nothing short of the application of prolonged dry or moist heat or immersion in pure carbolic acid can be depended upon to destroy this contagium.

II. Nutritional changes of the tissues which come within the immediate province of the dentist may be classified as (*a*) those due to hereditary non-contagious syphilis; (*b*) those due to congenital, active, and contagious syphilis; (*c*) those

due to the constitutional influence of acquired active syphilis; (*d*) those due to acquired syphilis that is no longer active, i. e., certain tertiary forms of the disease; (*e*) those due to nutritional disturbances produced by the remedies used for the cure of the disease. These varieties of nutritional disturbances require some special consideration. It is to be remembered that syphilis in the parents may manifest itself in the child in two ways: (1) As unequivocal syphilis; (2) in the form of what may be termed attenuated syphilis, which, properly speaking, is not syphilis at all, but comprises certain nutritive derangements incidental to a faulty constitution of the child due to the impression of constitutional syphilis upon one or the other or both parents. This has been generally overlooked, inasmuch as the physician is prone to classify such conditions under the more or less indefinite term of struma or rickets.

Parrot was not so far from the mark when he attributed rickets to hereditary syphilis. He, however, was inclined to term rickets "hereditary syphilis." As far as the relation of rickets to hereditary syphilis is concerned, I would say briefly that it consists merely of malnutrition incidental to a faulty constitution, which constitution is hereditary, and is due to malnutrition of the parents due to the syphilitic impression. It is not syphilis at all, and is not susceptible to the same treatment as true hereditary or congenital syphilis, but should be treated essentially upon the same therapeutical principles as rickets due to other causes of nutritional aberration. The same influence which syphilis is capable of imparting to the child through heredity may give rise to a faulty conformation of the jaws and a low grade of vitality of the structures of the teeth themselves, as a consequence of which irregularity of development, maxillary deformities, and premature decay may result. There is nothing specific about this relation of syphilis to dental pathology. On the contrary, this relation is a general and nutritional one.

The impression has been made upon me by the study of this subject that the *rationale* of the causation of these internal disturbances in the child is (1) a tropho-neurotic disturbance in the parents; (2) the transmission of this tropho-neurotic aberration to the child. The relation of tropho-neurotic disturbances to various manifestations of so-called "hereditary syphilis" is much more important than is generally believed. In fact, I have for some years held the opinion that many of the late lesions, and possibly some of the earlier ones, of acquired syphilis are due, not to the action of the specific virus *in loco*, but to nutritional perversions of a local character incidental to the impression of the syphilitic poison upon the sympathetic nervous system, the function of which is largely trophic.

(*b*) The lesions due to congenital and active contagious syphilis are in no wise different in their relations in dental practice from those of the acquired form of the disease. There is usually a clear history of the presence of the disease in the active form at an early period after birth, or perhaps at birth. Fortunately by far the majority of cases of congenital syphilis die during the first year, and those who eventually do come under the care of the dentist present lesions due to nutritional aberration rather than specific and active lesions. There are cases reported of hereditary syphilis in which the osseous lesions, particularly about the maxillæ and other bones of the face, have come at a very late period, but there is an element of doubt concerning a certain proportion of these, and in by far the majority of them previous lesions might have been detected had the cases been under careful and continuous observation.

(*c*) Active syphilis in the acquired form may produce a great variety of lesions of the mouth, jaws, and throat, mucous patches, ulcers, fissures, caries, and necrosis being the chief lesions. These are all contagium-bearing, and the dentist can not be too cautious in handling such patients.

(*d*) Under this head are certain carious and necrotic processes of the jaws and palate incidental to the tropho-neurotic influence of active syphilis. These lesions

are generally of a tertiary character, i. e., they belong, properly speaking, to the period of sequelæ. They are not supposed by many to be productive of contagion, although clinically they should always be regarded as possible contagium-bearing, inasmuch as it is impossible to tell positively at what time the active form merges into the period of sequelæ. They are always to be regarded, however, as septic. Necrosis of the palatal processes, nasal bones, and of greater or less areas of the superior and inferior maxillæ proper is frequent. It is generally supposed that these lesions are due to the pressure of the syphilitic deposit. By some they are attributed to the corrosive or local destructive action of the syphilitic poison. I regard these views as incorrect. The entire palate may be destroyed without any preëxisting pain, swelling, or any local disturbance which would be consistent with the view of pressure destruction of the bone. It will be found also that these lesions are limited by certain anatomical areas supplied by certain nerve filaments. The bone under these circumstances will be dissected out by the disease as cleanly as it could be done by the knife. A sufficient amount of cell deposit or local inflammatory action to produce complete destruction of one or both palatal processes of the superior maxilla could rationally be expected to be productive of great pain, local swelling, and other manifestations of the local destructive process. *Per contra*, very often the patient will present himself to us with a history of a small ulceration in the hard palate. The introduction of the probe will disclose, much to the patient's surprise, the presence of a sequestrum, involving, perhaps, the entire osseous tissues of the palate on one or both sides. I can not explain this peculiar condition upon any other theory than the existence of a tropho-neurotic disturbance which has so cut off the nutritional activity of the bone that death has resulted.

(e) It must be remembered that mercury used in excess or in special cases of idiosyncrasy is liable to produce inflammation or ulcerations of the mucous membranes, or carious and necrotic osseous processes that are in no wise different clinically from those produced by the disease *per se*. A fallacious notion exists in the minds of the laity, and I was about to say of the medical profession as well, that syphilis is a specific poison for which the natural antidote is mercury. As a corollary of this fallacious notion it is supposed that the larger the amount of the antidote short of killing the patient the sooner and more effectively the syphilis may be stamped out. As a result of this fallacious notion much damage has been done. If the nutrition of the patient be seriously impaired by mercury and iodide of potassium during the active stage of syphilis, it is a noticeable fact that as soon as the immediate effect of the remedies has passed away the syphilitic processes, favored by the constitutional debility induced by the remedies, not only break out afresh, but with renewed vigor.

I am aware that there are many deficiencies in the foregoing paper, but I trust that I have given this section food for reflection, and I rely upon the discussion to bring up many points which I could not well present in a paper of so general a scope.

---

## DENTAL MEDICATION AND EXPERIMENTS WITH CASES.

By V. A. LATHAM, F. S. S., F. R. M. S., D. D. S.,

*Northwestern University Woman's Medical School, Chicago, Ill.*

To-day we stand on the threshold of scientific investigation, more particularly, perhaps, in dental surgery and pathology than in any of the medical sciences, for so far this department has had to stand behind its fellows, shall we say by reason of its low position in the minds of both the public and the medical profession? Happily is it that Profs. Mills and Underwood came forward and gave their ele-

mentary work in the Transactions of the International Medical Congress in 1881, and Black in this country, and since then Prof. W. B. Miller, to whom the entire dental profession owe many obligations for his increasing and beneficial results in the field of bacteriology as allied to the dental profession. As yet few of our dental schools teach the sciences of histology, pathology and bacteriology as they should be taught, or even require their students to learn these subjects in the medical department. Is it not true that the dental surgeon has to deal with the body in almost the same character as the general surgeon? Can general and dental surgery be separated from one another at all when we consider the meaning of anatomy, sepsis, pathology, etc.? I think not, for who knows what disease has in store for him who decides to treat an abscessed tooth? Does he not have to consider histology, anatomy, and the relation of the tooth, the cause and condition of the tissues, the changes going on at the time, and the effects likely to be produced on them? Must he not also consider the dangers of sepsis, all its resultants, leading to perhaps deformity, loss of structure, and possibly of life? Under these conditions can we not urge that the students of to-day be more thoroughly taught if they intend to save and repair diseased organs? Does not the public understand the vast strides lately made in all scientific investigation and demand such training? How many of the students of this period realize the fact that scientific medication is needed, and not the empiric use of one remedy in every case simply because his training has been derived from some respected and eminent teacher who prefers creosote to cloves for all conditions, and who to save himself the expense and trouble is content with it. We see how difficult it is to know what remedy to use when we are not thoroughly acquainted with the physiology and histology, to say nothing of the pathology, of an organ. In dental science the question comes, how can we obtain the necessary amount of dryness without coagulation first being produced? The common agents all more or less belong to this group of coagulating substances, as, for example, alcohol, ether, air-heated chloroform, and many of the essential oils. This is a difficult subject to answer, the best and only true way being constant drying with absorbent paper, wool, and spunk; a thorough washing of the tooth in sterilized cold or warm water; then choosing an agent suited for the case, either deodorant, disinfectant, antiseptic, or germicide, provided it does not coagulate and so place a most formidable barrier to its own penetration by coagulating the albumin, as do carbolic acid, bichloride of mercury, etc. These agents must not be used, but one that has such a mixing and diffusing power that it is able to penetrate to a considerable distance and so permeate through all the substance likely to be dangerous, and at the same time not disturb or irritate the surrounding tissues in any degree sufficient to cause any molecular change, so producing a pathological condition. Therefore, to be thorough we must learn what drug is capable of miscibility in water, saliva, or mucus; in fact, what agent is readily diffusible through water, for in this locality we can hardly make an aqueous emulsion as we understand the term in pharmacy, agitation being impossible, the nearest approach being to saturate the cavity of the tooth with some essential oil not much, if any, heavier or lighter than water, which by application in such a degree will soon become almost, if not quite, a mixed solution on account of concentration, and so become a graded-strength solution exactly on the principle used in hardening material in graded strengths of alcohol. When we have done this it is clear we are approaching our object of having an antiseptic action which can be followed by a germicidal agent. When we have succeeded in destroying the microbes in the tissues, then, and not till then, is the time to use agents which have stronger actions and coagulating properties. Because at this point we can use coagulants most readily and these substances act as embalmers and protect the tissues from contact with the air and fluids of the mouth. They thus act as a safeguard against further inoculation of aerobic

germs and at the same time prevent the origin and growth of anærobic germs. From this, then, we gather that the most critical time in treating is during the withdrawal of water and the saturation by an antiseptic and germicidal non-coagulating agent. To find those remedies which are satisfactory is the present duty of experimenters in this line. Mechanical means, as capillary attraction, will do much to aid in the removal of water. No substance is of any value as an absorbent unless it can take up at least 5 centimeters in height of liquid, and so wood-wool, wood-cotton, and cellulose-cotton offer the greatest promise. Then thorough washing with listerine and peroxide of hydrogen, when the softened dentine can be cut away. Eucalyptus (Sanders's) will mix with listerine and gradually permeate the teeth. If we use some remedy which liberates oxygen we find it penetrates the tubuli and acts as an antiseptic, as a deodorizer, and as a bleaching agent. Then the tooth should be soaked thoroughly by a dressing of eucalyptus or some other non-coagulant and non-irritating oil, and the final cutting away of the dentine. I find the best plan is to permeate the tooth substance with some antiseptic oil for a few days, then to change the dressing and place a paste of aristol or iodol in eucalyptus or other oil over the dentine, then a plug of cotton, followed by a sandrach plug, and lastly a temporary stopping of gutta-percha or oxyphosphate. When this is removed the tooth can be dried by using warm, not hot, air, then chloroform or ether, followed by eucalyptus, and then if a stronger agent is desired carbolic acid will answer nicely, provided it is used strong, if the cavity extends to any depth and the pulp in danger of being reached. In superficial cavities a 1 to 40 solution can be used, but it must always be borne in mind that the weaker the acid the more it will penetrate, and judgment must be used in all the cases. Bichloride of mercury, if preferred, can be used in place of the carbolic acid, for they are both germicides and coagulants.

Another question of great importance is the testing of our coagulating albumin agents, by using antiseptics and germicides to see if they are able to penetrate this coagulum, for if this is possible we need not fear that we shall not be able to kill the majority of microorganisms present in any cavity. We can permeate the tubuli everywhere; yes, and even the pulp, and so produce a thoroughly aseptic tooth. In cases where we have large cavities, for example, in molars, where we wish to leave some softened dentine over the pulp in preference to exposing it, this will be one of the greatest gains in dental pathology, for sterilized dentine is unquestionably the best capping we can find; and if the agents used do not prove irritants to the delicate pulp the danger may be considered as past. In such cases as the above I have had great encouragement by the leaving of a paste of aristol and eucalyptus over the softened dentine, and capping over it, and temporary filling on that. Aristol combined with stearate of zinc, iodol, and iodoform can be used in the same manner by those who prefer them, using as an adjunct any of the volatile or essential oils which may be suited to the case. It must be remembered that the oils vary considerably in their chemical action, some being more diffusible, others said to be more powerful germicides, though this property is doubtful among them in the true sense of the word. Others, on account of the tannin they possess, coagulate quickly; others are stimulants to a great degree and even become irritants and vesicants. Oil of turpentine and terpinol, of Merck, are hydrocarbons, but myrtol and cassia are more potent as antiseptics than the other oils, but they are more stimulating and so irritating and must be used with caution near the pulp, or irritation or inflammation is liable to be produced. The oils are useful to mix with carbolic acid to diminish its escharotic power; they will also dissolve iodine compounds, hence their value in mixing with aristol, iodol, etc. They combine nicely with glycerin and some can be formed into emulsions, as they have a very slight solubility in water. There is no danger of discoloration of a tooth when a volatile oil is sealed in a cavity, for they all absorb

oxygen, and its power of bleaching is so well known as to need no comment; but the cavity must be thoroughly dried before introducing the oil. If we can dilute the fluids of the tooth, as the quantity is small, we can then use our coagulants with some degree of safety, for we can combine agents with diluted blood, albumin, etc., which will not produce quite such a heavy and impenetrable coagulum. In teeth where the pulp has been freshly removed immediate root filling is not safe as a general rule. In almost every case where surgical treatment has been required we have a wound, from which we have exudate, and this is almost always inflammatory. This secretion is liable to form a coagulum, and as blood serum is an excellent medium for bacterial growth we must watch and treat it most carefully. If the pulp has just been removed it is well to use some normal fluid, as salt solution, to wash out the root, in preference to water, as the exudate will be kept in a fresh state and not coagulated, and it can be more readily washed away and leave no deposit at the apex. When this is got rid of, soak with eucalyptus for a day, then treat with a mixture (E. E. C.)  $\mathcal{R}$ . eucalyptus (Sander's), 3 parts; Ol. cassia, 2 parts; eugenol, 1 part; mix. Carbolic acid, cloves, or any other agent can be used in place of the cassia if desired, and it forms a safe and pleasant antiseptic. Then after a day or two or a week the root can be dried thoroughly with chloroform, ether, or warm air, then bichloride of mercury, provided it contains tartaric or citric acid, which not only keeps the solution but aids somewhat against coagulation or, if preferred, crystals of carbolic acid may be placed in the root and a hot probe passed down. The heat melts the acid and cauterizes at the same time. Then fill the root with gutta-percha, dissolved in equal parts of eucalyptus and chloroform, the pulp chamber with cement, and then finish with gold. Naphthol and naphthaline are excellent antiseptics and are useful for pulpless teeth, as they do not become stained. As antiseptics they are very valuable where a dressing is required for exposed pulps, as is also the mixture given above. It is cheap, simple to use, deodorant, and induces a rapid growth of healthy granulations.

In microcidine, a compound of naphthol and sodium hydrate, we have a germicide and inhibitor of germ growth. It is ten times as powerful as boric acid. In a solution of  $\frac{3}{1000}$ , which is the strength for general use, it is a most excellent wash where there is a free discharge of pus and produces no irritation of the mucous membrane. It also prevents fluids from becoming putrescent, especially urine, for thirty-six hours. It has a great advantage by being very soluble in water; neither does it corrode instruments, nor stain clothing or tissue. Iodine water is a most excellent antiseptic fluid for irrigation of suppurating wounds, as it is for fresh wounds, and as it is a normal fluid its effect on the blood and pus is simply to keep them liquid. It is of especial value in dying or suppurating teeth.

What do we mean by permanent antiseptic dressings of wounds, and what are their desired qualities? We mean a dressing applied immediately after an operation and left till the wound is healed. The qualities we should try to obtain are: (1) As perfect hæmostasis as possible. (2) Absolute asepsis of the wound or part. (3) Perfect drainage. (4) Sanguineous oözing reduced to a minimum, rapid absorption of any liquid by the dressing, and especially if in deep cavities. (5) Antiseptic action to be exercised by the latter upon the liquids which impregnate them, and so preventing decomposition, fermentation, and putrefaction. (6) Coagulating agents must be avoided until the tissues are antiseptic, and then and not till then can such germicidal agents as carbolic acid or bichloride of mercury be used. (7) The absorption even in small quantities must be watched, and especially in iodoform and mercury, from both of which poisoning and irritation are liable to result. (8) Mechanical and chemical indifference (irritability) to the edges of the wound.

Aseptol (sulpho-carbo-ortho-oxyphenyl-sulphurous acid) is a syrupy, rose-colored, volatile liquid, with a strong odor, and is non-irritant. It has the following good qualities as proven by numerous experiments. (1) Aseptol readily dissolves in every proportion of water, alcohol, and glycerin. (2) It is more acid, but at the same time less caustic than carbolic acid, and it directly combines with bases. (3) It is perfectly harmless. (4) Its anti-fermenting, anti-putrid, and disinfectant properties are more energetic than those of carbolic and salicylic acids, and so it recommends itself as a substitute for carbolic acid, and is a valuable hygienic agent. (5) It can be combined readily with essential oils. A mixture of carbolic acid 67 parts with resorcin 33 parts, to which 10 parts of water have been added gives a liquid mixture which will remain so, and is soluble in all proportions with water, and its use as an efficient and convenient antiseptic preparation is readily seen. Sulpho-carbolate is a useful agent for dental work, as it is readily soluble in distilled water or alcohol. A solution of 10 to 15 per cent destroys microorganisms entirely, while a 5 per cent solution only arrests their movements. Wool and dressings are readily impregnated with the salt, and in consequence of its trifling volatility the antiseptic power is retained for a long time. It is non-poisonous, non-irritant, does not produce local anæsthesia or eruptions even if applied to the mucous membrane. It is useful as a powder and can be combined with other agents. Some consternation was caused to members of the profession when Dr. R. B. Miller's paper on Iodoform appeared in the Dental Cosmos. If these experiments are true, why is the drug so much used in hospital and medical practice in spite of its disagreeable and dangerous qualities? Has not the preparation of the drug, its solutions, and methods of application a great deal to do with these bad results? I think if the drugs can be prepared in a sterile way such trouble and misunderstandings could be obviated to a large extent. Iodoform may be used in several ways: (1) In very fine powder; (2) pencils either made with gelatin which is elastic; cocoa butter, wax, etc., which are rigid; or pencils of 5 to 10 grains of the drug are excellent, and can be made like the nerve-filling points; (3) iodoform gauze (10 to 50 per cent solution in either) for wounds, drainage, etc.; (4) as emulsions, iodoform 10 to 50 per cent, glycerin and water equal parts, and tragacanth O. 25 per cent or with oil, for wounds of joints, abscesses, etc.; (5) iodoform 1, benzole 9, zanolin or vaseline 11, and oil eucalyptus 2 minims, injected in lymphadenitis. So far no trouble has occurred in the use of iodoform when sterilized. I use olive oil sterilized by boiling, or some of the essential oils. The iodoform is added after cooling the oil, 10 per cent by weight. The vessel in which the oil is received is previously sterilized by washing and followed by sublimate solution, the bichloride being washed out by ether or alcohol, the former being preferable. The best preparation of iodoform is that prepared by means of electrolytic action according to the method of Schering. The inflammatory reaction so often noticed is not seen after thorough sterilization. Even when used as an emulsion in tuberculosis, etc., the results are excellent. A useful antiseptic mixture is that recommended by C. Cavazzini, composed of iodoform 55 parts, salicylic acid 20 parts, subnitrate of bismuth 20 parts, camphor 5 parts, or I prefer to add an essential oil in place of the camphor, for then we get both the oil and camphor effect. For indolent granulations in sinuses it quickly stimulates them, and suppuration rapidly disappears. Iodoform, either pure or in strong solution, has a very striking effect upon the nerve endings. It is more powerful in this respect than carbolic acid, its effects are more lasting, and it is of great value in suppurating pulps and where sensitiveness still exists through the odontoblast cells being irritated or dying after removal of pulps by arsenic or by nerve extractors. A drug which so far is fighting for its existence in the vast field of materia medica, and which is so closely allied to iodoform, is dermatol. As yet it is upheld and condemned by many in the profession, but in my hands it has shown itself worthy of considerable further trial. It was first discovered by Heintz

and Liebrecht, who convinced themselves of its freedom from poisonous properties by experiments on animals. Doses up to 45 grams, repeated for several days, proved entirely harmless to rabbits, while  $1\frac{1}{4}$  drams *pro dosi* was given by stomach tube to dogs and rabbits and no toxic effects seen. As an antiseptic agent it prevents putrefaction, and also the development of bacteria when used as a 1.10 per cent solution. Poisoning by internal administration of bismuth salts has been very rarely seen, as they are not readily absorbed from the alimentary canal; yet they can be absorbed from the surfaces of wounds, ulcers, and lead to severe poisoning with symptoms similar to those of mercury. (Dermatol introduced in amounts of 30 to 45 grains into subcutaneous tissue pockets in animals, and also when placed in contact with the peritoneum, produced no symptoms of illness nor were any pathological phenomena found after killing the animals.) Experiments on human beings in surgical, medical, obstetrical, and gynecological cases showed it also to be harmless.

The harmlessness of dermatol in contrast to such bismuth salts as the subnitrate of salicylate seems to be due to its insolubility and constancy. Bacteriological experiments made under conditions as closely as possible similar to that which obtains in the living body, at a temperature of  $37^{\circ}$  C. under exclusion of light and in the presence of moisture, after first sterilizing the dermatol by steam and control experiments made, the results were negative, except where the drug was scattered in very thick layers over the inoculated areas. This effect is also seen when iodoform, iodol, or aristol are used in the same way. Dermatol is chemically a basic gallate of bismuth, is an exceedingly fine saffron yellow powder, closely resembling iodoform, which is not hygroscopic nor shows any effect by the action of air, light, or heat, and in this manner is superior to all the above-named agents. It is tasteless and odorless, innocuous, in a high degree exsiccant, and promotive of granulation. The subgallate of bismuth will stand a temperature of  $212^{\circ}$  F. It is relatively insoluble and has a fatal action upon bacteria when in immediate contact with the substance to be acted upon. Dermatol is rapidly absorbed, and aids healing by its drying influence on a wound, since by withholding from the bacteria the fluid which is essential to their growth, it brings about their destruction, and also, by virtue of its kolyseptic action, viz, its restraining influence upon the development of bacteria, it is destined to take a permanent position among the drying antiseptics. What are the advantages? (1) It can be rubbed into gauze, then sterilized by heat or steam without altering the chemical nature of the drug or destroying its properties. (2) It saves the unpleasant necessity of changing dressings so often and is of especial value in freshly sewed bowel wounds and in perineoplasty. (3) It protects the wound as no other remedy can, and enables the surgeon to remove sutures much earlier than where other applications are used. (4) Gauze impregnated with dermatol and used as tampons is of great value in the treatment of vaginal catarrh. (5) Dermatol suppresses secretions, whilst iodoform increases them. Glaesar thinks iodoform is better applied to putrid wounds and suppurating tracts than dermatol, the last being used only when the wound is already antiseptic. (6) For diarrhoeal affections, in typhoid fever, dysentery, phthisis, etc., it has no equal. Dose, ss., in 4 doses. (7) For burns from either fuming nitric acid, hot water, or hot fat it is excellent when applied as a salve. (8) In diseases of children, as 10 per cent with vaseline or lanolin on lint, gauze, etc. In otitis media, as a powder blown in. In skin diseases the drying properties are especially useful. (9) In surgery, strongly secreting wounds, ulcers, abscesses, etc. Methods of use: As powder, through insufflator, on gauze, dusting; as liquids and pastes, in emulsion of collodion, glycerin, essential oils; as ointment, with lanolin, wax, zinc oxide, or paraffin. (10) Wounds always heal without local reaction, febrile symptoms, or suppuration, and by the absorbing power it abstracts the moisture and so deteriorates

the nutritive value of the tissues. In dental surgery dermatol gave excellent results in chronic alveolar abscesses, both with and without fistulous openings, suppurating pulps, inflammation of the gums, and pyorrhoea alveolaris.

*Case 1.*—In one case, which will do for a type of all, I found the patient, a lady, age 18, had a large abscess on the buccal surface, extending over the second superior bicuspid and first superior molar of the left side. A large cavity in the coronal, proximal, distal side, which, after applying the rubber, I washed out with warm sterilized water and cut down and beveled the enamel walls. Then drying the tooth as well as I could with bibulous paper, spunk, etc., I applied a pledget of wool with pure listerine (Lambettes), soaked the cavity, then cutting the débris and softened dentine I soon opened up the pulp chamber and root, and then reached a quantity of greenish-yellow pus. This I washed out with listerine and then cleansed with a rough probe and a smooth one with bibulous paper on it in preference to wool. I then washed out with listerine in preference to peroxide of hydrogen, as an accumulation of free oxygen is not good unless a direct outlet is present. I then introduced eucalyptus and left it in contact, but loose, followed by a dry plug of wool and then another dipped in sandrach varnish. After removing the rubber I opened the pus sac freely, after first touching it with carbolic acid to render it painless and antiseptic, well washing out the sac with sterilized warm water, peroxide of hydrogen, and finally packing with gauze dipped in the mixture E. E. C., above given. The patient had allowed this condition to become chronic, and a good deal of chronic inflammatory tissue was present through the occurrence of continual cicatricial openings. In the R. S. first molar was a large cavity and three small abscess sacs over the buccal surface, and a fistulous opening from the palatine root; also a long-standing case. This was treated in a similar manner, and the patient told to come the next day, when the canals were well cleansed, oil of cassia in the left bicuspid and eucalyptus in the right molar, the wound cleansed, and fresh gauze inserted. Good results followed until about two weeks after, when an increased discharge showed in the left bicuspid, which seemed difficult to get rid of, as it was apical and the abscess was still well open. I then washed it thoroughly and made a paste of eucalyptus with dermatol, and with fine nerve probes, etc., forced up all I could, and even through the apex, covered the paste, and put in a temporary gutta-percha filling, as the patient wished to go away for a while. After two weeks, on removing the stopping, I found considerable of the drug absorbed, what was left being a fine dry powder. This I wiped out thoroughly with eucalyptus on bibulous paper, and then dried with chloroform and finally ether; inserted dry cotton, plugged temporarily, and after a week, as no bad results showed, I filled the roots and crowned, and so far have had no further trouble. The right side gave much trouble, and as a final resort I used dermatol in it with excellent results.

*Case 2.*—A young boy with a cut in the sole of the foot, which had been very badly neglected for two weeks; pus present in great quantity; much odor and pain. The foot was carefully washed in sterilized water, the necrotic epidermis, etc., cut away, and the wound covered with dermatol in a thin layer. This improved the condition. At the next dressing the drug was dusted over in a large quantity, covered with oil silk to prevent adherence of the dressing to the wounded surface, the whole bandaged, and as the boy would not keep quiet the case seemed likely to require some time to heal. But after a few days, the dressing being left undisturbed, the result was most gratifying; suppuration ceased, the remaining necrotic tissue was thrown off, under which the granulating surface was rapidly formed, and without irritation covered with epithelium.

In experiments with cultures of staphylococcus the growth stopped on applying dermatol. Bacteria (12 different varieties) were cultivated on agar jelly. Three tubes were in each case inoculated, one of which for control purposes was left free from the agent. Over the surface of the second, dermatol was very lightly scattered by a spray apparatus, while the third was thickly covered with dermatol. One species of staphylococcus showed the most flourishing growth after three days in the control tube, while in both the others, where dermatol was scattered, not a trace of the development could be discovered. On the fifth day the surface of the two latter was scattered with a needle and fresh inoculations were made; neither here did any growth occur. Agar, colored with indigo-carminé, 1 per cent, and 2 per cent of dermatol, added in each of two tubes, A and B, well mixing the liquid and pouring out in cold Petri dishes. In a third tube, C,

no dermatol, staphylococci introduced, and the whole placed in the incubator. In C decoloration after three days, while in A the same stage was not reached in the dish till the tenth day; in B not till the fifteenth day. *Vibrio Finkleri*, *Vibrio cholerae Asiatica*, *Bac. Syphi. Abdom.* showed difficult and limited growth under the influence of dermatol; while with *M. Tetragenus* and *Bac. subtilis anthracis* the cultures remained quite sterile.

These few points show that dermatol is likely to prove very advantageous in dentistry and in medical work, but it requires a good deal more careful examination to prove its exact position. A fact to be remembered is that for the dose of a drug to act antiseptically it is not necessary that the dose of the drug employed be able to kill the microbe; it is sufficient that such a dose enables the leucocytes to triumph over the germs in question. Often the same amount of, say, the mercuric salt diminishes the power of both kinds of bodies, but it is important that the action exercised be such as to enable the leucocytes to conquer, as it were, the microorganisms. The aim, as we all know, is rather asepsis than antiseptics, the prevention of germs from gaining access to wounds instead of attacking them only after they had got there. The more rapidly wounds and other lesions can be closed up and repaired, by so much is the risk of bacterial infection reduced. Hence the demand for wound-healing agents in practical surgery and dentistry; and so long as we must use them, it behooves all who have these agents in active work to contribute their results from time to time with carefully recorded cases for or against these agents, so that after a time many unreliable and needless drugs could be set aside.

### BREVE NOTICIA SOBRE A ARTE DO DENTISTA NO BRAZIL.

POR ARISTIDES BENICIO.

Até o anno de 1881 não havia nas faculdades de medicina do Brazil curso de cirurgia dentaria nem tão pouco instituto particular onde se podesse preparar o aspirante á profissão do cirurgião dentista. A aprendizagem era feita extra-officialmente.

O individuo que pretendia exercer essa profissão requeria á faculdade de medicina exame de habilitação para o referido exercicio. Esse exame constava da descripção anatomica de um dos maxilares, do modo porque se obturava um dente e como se fasia uma dentadura; d'isto constava a prova oral. A prova pratica era... a extracção do dente no cadaver! Erão examinadores os lentes da faculdade em numero de tres.

Não era exigido nem um só preparatorio, razão porque encontra-se no Brazil dentistas quasi analphabetos, alguns oliór bons praticos.

Em 1882, reformando-se o regulamento das referidas faculdades, creou-se um lugar de preparador de cirurgia dentaria, lugar que só pode ser exercido por um cirurgião dentista. Creou-se mais nessa mesma epocha os cadeiros de anatomia, phisiologia, pathologia e therapeutica dentarias, professados, porém, pelos lentes

substitutos dos respectivos cadeiros (doctores em medicina). Ao preparador competia explicar prothese e trabalhos de gabinete. Exigio-se de então para cá as tres provas—escripta, pratica e oral. Começou d'ahi a cirurgia dentaria a progredir entre nós.

Hoje, depois de subseqüentes reformas, já temos um instituto odontologico annexo ás faculdades de medicina com um curso senão completo, pelo menos regular, pois alem dos cadeiros acima temos mais a de clinica odontologica e a de prothese dentaria, que têm por professores cirurgiões dentistas.

Já se vê que pelo andamento que tem tomado nestes dez ultimos annos a cirurgia dentaria no Brazil, será de progressiva senda e brilhante futuro neste paiz a profissão do dentista.

Ha dez annos não se cogitava do exercicio do dentista nos estabelecimentos publicos, nem nos hospitaes; hoje contamos no primeiro estabelecimento de caridade brasileiro—o Hospital da Santa Casa da Misericordia—(um dos primeiros do mundo) um excellente gabinete de cirurgia dentaria, onde funcção effectiva e diariamente dous dentistas, o director do consultorio e o seu adjuncto. O Recolhimento dos Orphões, a Casa dos Expostos, o Hospicio de Alienados têm bem montados serviços de cirurgia dentaria dirigidos pelo mesmo profissional que se acha á testa do referido serviço no Hospital da Santa Casa. A Beneficencia Portuguesa tem tambem, no seu hospital montado, o serviço dentario. A Brigada Policial conta no seu corpo sanitario um cirurgião dentista, bem como o Collegio Militar, alem de outros estabelecimentos e corporações publicos e particulares que sustentão serviço identico.

Referindo-me ao instituto odontologico esquivia-me mencionar os cadeiros da hygiene e hystologia, e declarar que para a matricula no instituto o candidato tem apresentar certidão de exame das materias preparatorias: portuguez, inglez ou francez, arithmetica, geometria, phisica e chimica.

Tudo isto prova que a arte do dentista progride a passos largos nos Estados Unidos do Brasil.

Junto remetto algumas estatisticas do serviço a meu cargo no Hospital da Casa Santa. Não é um trabalho completo, ao contrario está longe d'isso, é, porem, o inicio de futuros estudos e observações, quiçá, proveitosos.

*Observações.*—Além das operações mencionadas foram praticadas mais duas reimplantações com o mais feliz resultado; sendo uma a de um incisivo central affectado de periodontite chronica e duplamente fistuloso, em uma senhora de 30 annos mais ou menos; e outra a de um premolar tambem fistuloso, em um menor de 16 annos. Segundo as observações feitas durante o anno neste Gabinete póde-se estabelecer approximadamente nos dentes attingidos pela carie a seguinte media: Incisivos superiores, 6 per cent; incisivos inferiores, 1 per cent; caninos superiores, 2 per cent; caninos inferiores, 1 per cent; premolares superiores, 12 per cent; premolares inferiores, 7 per cent; grandes mol. superiores, 22 per cent; grandes mol. inferiores, 49 per cent. Notando se ainda serem os dentes do lado direito mais perseguidos pela carie, exceptuando-se os incisivos inferiores que são atacados igualmente de ambos os lados, e os premolares e grandes molares superiores que apresentam um pequeno accrescimento na média para o lado esquerdo.

| Junho .....     | 285                     | 8               | 9                       | 1                          | 1               | 3               | 0             | 2              | 0             | 0              |
| Total .....     | 4,881                   | 64              | 59                      | 3                          | 21              | 35              | 9             | 11             | 1             | 1              |

*Observações.*—As consultas em numero de 6,074 com o consta do presente Mappa foram dadas a 4,242 pessoas matriculadas durante o anno no respectivo livro, sendo 1,424 homens, 1,625 mulheres e 1,193 creanças. Continuando as observações relativas aos dentes attingidos pela carie foi obtido o mesmo resultado do anno passado, com pequenas differenças, podendo ainda estabe-  
lecer-se a seguinte média: Incisivos superiores, 6 per cent; incisivos inferiores, 1 per cent; caninos superiores, 2 per cent; caninos inferiores, 1 per cent; premolares superiores, 12 per cent; premo-  
lares inferiores, 7 per cent; grandes molares superiores, 22 per cent; grandes molares inferiores, 49 per cent. Nos incisivos superiores e nos grandes molares superiores e inferiores nota-se que são attingidos pela carie mais os do lado esquerdo do que os do lado direito dandose justamente o contrario com os premolares superiores e inferiores, sendo entretanto os incisivos inferiores e os caninos superiores e inferiores atacados igualmente de ambos os lados. E' nesta ultima parte que existe a differença entre as observações deste anno e as do anno passado, pois somente quanto aos incisivos inferiores e grandes molares superiores ellas combinam, divergindo quanto aos outros. Em subseqüentes observações chegar-se-á a um resultado definitivo.

*Observações.*—Pelo estudo comparativo das idades, em relação á carie dentaria e outras moles-  
tias dos dentes e seus annexos, nas observações aqui feitas, chegamos ao seguinte resultado: A  
idade mais critica, isto é, aquella em que mais se manifestam esses estados morbidos, é a que  
medeia dos 16 aos 30 annos, quer no homem quer na mulher, tendo esta um augmento sobre aquelle  
de 33 per cent mais ou menos. Partindo d'ahi poderemos estabelecer a seguinte média approxi-  
madamente: Dos 31 aos 40 annos ha decrescimento de 75 per cent para o homem e de 80 per cent  
para a mulher; dos 41 aos 50 annos ha para aquelle uma diminuição de 85 per cent e para esta de  
91 per cent; quanto aos maiores de 50 annos a differença é de 89 per cent para o homem e de 95  
per cent para a mulher. D'ahi conclue-se que dos 16 aos 30 annos a mulher é mais sujeita ás  
affecções dentarias, tornando-se o homem mais susceptivel das ditas affecções dos 31 annos em  
diante. Cumpre notar que nos maiores de 50 annos nas observações feitas apenas apresentam 3  
comidade superior a 68 annos. Quanto ás idades inferiores a 16 annos, reservamol-as para  
futuras observações. Não temos a presumpcao de offerecer como exactos estes dados estatís-  
ticos; elles representam apenas o começo de estudos que continuaremos com o preciso zelo e  
escrupulo, podendo chegar mais tarde a um resultado, senão definitivo pelo menos approximado.

*Observações.*—A proporção das pessoas matriculadas este anno neste consultorio foi a seguinte quanto a nacionalidades: Nacionais, 71 per cent ; Portuguezes, 20 per cent ; Italianos, 5 per cent ; Hespanhoes, 1½ per cent, e 2½ per cent para as nacionalidades seguintes, guardando a mesma ordem de proporção: arabes, africanos, allemães, austriacos, paraguayos, francezes, gregos, americanos, orientaes, suecos, suissos, chins, argentinos, inglezes, turcos e holandezes. Quanto ás idades, póde-se tomar a média de 70 per cent para a idade dos 16 a 30 annos ; 20 per cent dos 31 aos 40 ; 7 per cent dos 41 aos 55 e 3 per cent para os maiores de 51 ; prevalecendo em maioria as mulheres em todas as idades ; divergindo das observações do anno passado neste ponto, as quaes demonstraram que a mulher era mais sujeita do que os homens ás affecções dentarias, dos 16 aos 30, dos 31 em diante, porém, tornava-se o homem mais susceptivel das referidas affecções. Como pretendemos continuar as nossas observações, sempre com todo o escrupulo, esperamos chegar a um resultado que com mais segurança nos possa fornecer dados, senão exactos, pelo menos muito approximados neste e em outros pontos de nossas observações.

ADDRESS BY THE PRESIDENT OF THE SECTION, ALBERT L. GIHON,  
A. M., M. D.,*Medical Director, U. S. Navy.*

## SANITARY MOTES AND BEAMS.

And why beholdest thou the mote that is in thy brother's eye, but perceivest not the beam that is in thine own eye? (St. Luke, vi, 41.)

These words of the Teacher of Humanity, which "the beloved physician" of the first century has recorded, are an appropriate text for the opening address in the important section with whose conduct I have been charged in this congress. Time was, and that no long time, when Hygeia, the neglected Cinderella of the medical family, slunk unnoticed among menials; now that she graces the salon, her proud sisters caress her and suitors court her favor. As an old admirer of this fair mistress, whose colors I have worn through youth and manhood, I may be pardoned the personal exultation that I have lived to see her *suzerain*. The ascendancy of hygiene has greatened and glorified medicine, without dimming the luster of any other branch; but though her cult is established, her mission has not ended with the recognition of her supremacy and the faithful following of her own ilk. To-day she turns to the people and their rulers, outside the medical fold, and demands the place in their councils that is hers of right. A makeshift share in the administration of the sanitary interests of the country has been grudgingly allowed, but the inexorable demands of modern enlightenment can not be satisfied until the conservator of the public health shall sit a peer among the rulers. The minister of war may build mighty engines for destruction and defense and muster vast armies and navies, which disease can disperse with a weapon so tiny that the eye can not discover and no mere military expedient antagonize. The minister of finance may fill his treasure houses with gold and silver by the ton, which can buy human souls, honor, virtue, independence, everything but the boon of health, God's free gift to man, through which alone he can be like His own glorious image. Commerce, agriculture, manufacture, fishery, mining, and all the industrial occupations of the human race, which are now the objects of the intelligent supervision of cabinet ministers, who are grand masters of political economy and social science, can not thrive without vigor of human blood and brains and brawn, which are the machinery of these occupations; yet until this decade it has not been thought that the intelligent supervision of a grand master of the divine science of medicine was necessary to preserve this vigorous health of the community, without which even these other ministers can themselves only imperfectly perform their own offices of administration.

When I entered the service of the Government of the United States as an officer in the medical department of the Navy, nearly forty years ago, with a minimum of experience and a maximum of enthusiasm, and an exalted opinion of the dignity and responsibility of my charge which a lifetime has only intensified, I was astounded at the total ignorance of sanitary provision then prevailing in the naval service. Medical officers were curtly reminded that their opinions and advice would be asked when desired; their protests at acts that filled the hospitals and mortuary lists were contemptuously unheeded; they were reproved for officiousness and punished as insubordinate. Disabled sailors and marines were discharged, and their places and those of the dead were filled without regret or remorse, but with the shameless boast that "if men die we can ship others," like the Netherlands commodore, some of whose crew had been killed, by the careless firing of a shotted saluting gun, who accepted the apology for the accident with the

nonchalant remark, "Dere are plenty more Dutchmens in Holland." The battle ships and cruisers of modern navies are not more unlike the brigs and sloops of war of forty years ago than are the cleanly, well-fed, comfortably clad, and cared-for enlisted men, who go on shore daily, subscribe for newspapers, and write letters, a different race from the begrimed and degraded "shell backs," who were ordered to their work with curses and punished with brutality for offenses which neglect and ill treatment had incited. The naval and military establishments have considered the beam in their own eyes, but civil authorities are still purblind to the necessity for organized intelligent sanitary supervision and direction, and grope for succor only under the flash-light of a pestilential visitation. The following from a recent editorial in an influential journal is pertinent:

Whether cholera has or has not made its appearance at Chester, which is practically one of the suburbs of Philadelphia, it is certain that the conditions reported to exist there are in the highest degree favorable for the introduction and spread of that disease. All accounts represent the neighborhood in which the alleged cases occurred as filthy beyond description and occupied by a class of persons who pay no attention whatever to the laws of health or personal cleanliness. Of course the country now has the pleasant assurance that the place is to be thoroughly cleaned and effectively quarantined; but why were not the steps necessary for the protection of the public health taken before the resulting disease, whether cholera or not, had gained such a footing that already five persons have died from it? The time to lock the stable door is before the horses housed therein are stolen, and the way to treat contagious diseases is to prevent their appearance, and not wait for them to gain a foothold and then try to stamp them out.

The secretary-general has announced that the proceedings of this section and its congener, the Section in Marine Hygiene and Quarantine, will constitute a special feature of this congress. It is therefore incumbent upon us before adjourning, to declare very positively the opinion of the members of this section, composed of experienced practical sanitarians from every country of the Western Hemisphere, that the interests of the public health must be intrusted to a department of the Government especially charged with their administration, with equal independent executive authority as given to other national departments. Temporizing legislation under the spur of emergencies does not befit this age. As the enlightened physician seeks to prevent his charges becoming ill, so should the guardian of the public health be able to forestall these emergencies, whose pecuniary cost, in money expended and wasted, in trade paralyzed and diverted, in labor and its wages lost by the sick and terrified and dead, in a single epidemic, exceeds that of maintaining an efficient sanitary service for the whole country for a whole year. The fault of the medical profession has always been its lack of bold assertion of its rights; but it can no longer hesitate to declare to trade and commerce and agriculture and manufacture that the health and vigor which are essential to prosperity can not be secured by their own unskilled, uninformed efforts. They must learn, as the military services have learned, that powerful armies and navies are the results of able and untrammelled medical departments. It is as unwise to confide the care of the national health to a financier, however astute, as to expect a postmaster-general to understandingly control a bureau of agriculture, or a fishery commissioner to best administer the affairs of the public schools, and an attorney-general to direct the mining industries. The health of a nation is a national consideration involving international coöperation. There should be no priority nor clash of sectional interests. State lines are not respected by epidemic intruders. No State barrier can be so defensive and impenetrable that the toxiferous germ can not pass through. The precise form of administration may be left to legislation, the indispensable requisites being that it shall be national, that it shall have parity of voice and influence in the national councils, that it shall have independent executive authority under the limitations common to other departments, and that it shall

be intrusted to educated and experienced medical men, who alone are competent to assume its responsibilities.<sup>1</sup>

I have not wandered from my text in thus pleading for a national public health establishment. Spasmodic tentative provisions in emergencies are nothing but attempts to discover *motes* from abroad when the *beams* at home should first receive consideration. To parallel further and in another sense, the scientific tendency of the day is literally toward mote hunting through microscopes instead of using our human eyes upon visible abominations. The sanitarian, official or amateur, need only look about him to be appalled at the spectacle of indifference of rich and poor, high and low, to dangers far greater than any from cholera microbes which confront them every hour, and it may be worth our while to indicate some of these beams in our own eyes, which we complacently refuse to see, while we magnify the motes on our horizon. The preventable disease, which kills more of the human race than cholera and yellow fever together, and in its ordinarily slow process of killing lessens the productive power of a community, directly by the enfeeblement of its victims and indirectly by its demands upon members of households and eleemosynary institutions for the care of these chronic invalids; tuberculosis is tolerated with as little concern as the Mongolian exhibits for small-pox or the creole for yellow fever and malaria. The consumptive, whose traits no professional acumen is required to recognize, frequents our crowded thoroughfares, sits beside us in unventilated street cars and at the hotel table, occupies Pullman sleeping births, and shares the steamship stateroom, wholly unrestrained and innocently ignorant that he or she may be sowing the seeds of disease among delicate women and children. Anyone may verify this who uses his eyes for the purpose along the railway and coastwise steamer routes to our invalid resorts. Within a twelve month, on my way to Mexico by rail, I was fellow-passenger with two invalids in the advanced stage of phthisis, en route for San Antonio, one of whom occupied the opposite berth and the other one diagonally across the car, so that I could see and hear them coughing and expectorating, with only such attention as well-intending but unskilled relatives could render. They had no vessels for receiving their sputa, which were discharged in their pocket handkerchiefs to be scattered over pillows, coverlets, and blankets. They left the car in the morning, and I saw those same berths: it is true with change of linen, sheets, and pillowcases, but with no change of blankets, mattresses, or pillows; occupied that very night by other travelers, who were thus subjected to contact with a pathogenic microbe far more tenacious of life and power of evil-doing than the dreaded cholera spirillum. One has only to sit in a crowded street car on a winter day and watch the clouds of respiratory steam circling from the mouths and nostrils of the unclean and diseased into the mouths and nostrils of the clean and healthy, as the expiratory effort of the one corresponds with the inspiratory act of the other. The road is short but straight and sure from vomica and mucous patch to the receptive nidus in another's body. Who that has ever had forced upon him an aerial feast of cabbage, onions, garlic, alcohol, tobacco, and the gastric effluvia of an old debauché can doubt that aqueous vapor can transport microscopic germs by the same route? Not long ago I traveled by sea from New York to Charleston, and for two nights was cabined with some twenty consumptives going to Florida. The air was chilly and they huddled around the stoves and fearfully and fearlessly closed doors and windows until the atmosphere became stifling and

---

<sup>1</sup> These propositions were unanimously adopted in the form of a resolution in these terms by the conjoined Sections in Hygiene, Climatology, and Demography, and in Marine Hygiene and Quarantine, and reported to the general session of the congress, by which it was referred to the international executive committee, which returned it with its indorsement and direction that it be transmitted as the voice of the congress to the executives of all the countries represented therein.

surcharged with their emanations and the dried sputa, which they ejected on every side. It was comparatively easy to escape during the day by staying on deck, and I slept with my stateroom windows wide open, but the curtains, carpets, pillows, and mattresses had been saturated by I know not how many expectorating predecessors. I have visited fifty smallpox cases a day, have gone through yellow-fever wards, and stood by cholera bedsides with far less apprehension than I experienced on that trip; yet it was one taken by many thousands of people who would have been terrified to know that there had been a case of cholera within a mile to leeward of their homes. Recall in your several experiences the instances of members of a family who have occupied the same chamber and bed with a gentle and beloved aunt or sister, and those of tuberculous husbands or wives, who have become ill like them with pulmonary phthisis attributed to everything but the manifest cause.

In former years I preached a crusade against another virulent communicable disease, in the interest especially of innocent and helpless women and children, and for a time I was gratified to find that husbands and fathers began to realize, from the numerous indisputable instances of innocent infection I was able to report, that syphilis might be, as it had been, contracted from combs and brushes and rough-edged drinking vessels in hotels, sleeping cars, and boarding houses, from pens, pencils, and paint brushes that had been held between diseased lips, from dirty old bank notes, from street-venders' toys, from a lover's kiss, a stranger's caress, or a nurse's ministrations. Supported by an array of cases of infected children, young girls, and elderly men and women, the committee of the American Public Health Association, of which I was chairman, advocated the enactment of a law placing venereal disease in the category of other communicable affections and punishing its transmission as a misdemeanor; but there were too many of the self-righteous blind to these beams in their eyes, who thought it wiser to seek to exterminate by ignoring its existence and never uttering the name of a disease that has done more harm to mankind than all the diphtheria, typhoid, smallpox, measles, and scarlet fever which are so carefully isolated and their statistics so regularly collected and promulgated; a disease that travels with the missionary to Asia, Africa, and the Pacific, and decimates bodies faster than he can whiten souls.

I do not expect that all who have eyes will see as I do, or, having ears, hearken to what I say. The idle and perverse generation of the first century will have its following in the twentieth, and men and women will continue to do the insanitary things they ought not to do, and leave undone the sanitary precautions they ought to take, despite our warning, our imploring, our advice, or our denunciation. However benevolent and beneficent the hygienist's aim, his unappreciated, unrequited, and often unprofitable labor is enough to deter him from what has been derisively described as only an effort to procure the survival of the unfit, and thus thwart Nature's own attempt to rid the world of them. He encounters another obstacle to success as aggravating as the disbelief in the necessity for his work. The authorities listen to his warnings, and then employ their own perfunctory and superficial methods of protection. Told that absolute cleanliness is the fundamental fact of sanitation, street cleaners are set at work brushing the surface dirt into little heaps, which passing vehicles again distribute, or the winds carry into the open windows of adjacent residences. The refuse of the household is deposited in vessels on the sidewalks of crowded thoroughfares, to be emptied after a time into collecting carts, from which clouds of dust envelop passers and circulate back into the houses; living dust, for Manfredi found an average of 761,521,000 microbes to the gram of the street dust of Naples, from which he cultivated pus, malignant edema, tetanus, tubercle, and septicæmia. Swarms of flies feed on the decomposing contents of exposed garbage pans and buckets, and carry their tiny germ-laden booty into the butcher shop of the poor and the kitchen of the millionaire. Who can dispute that if the hair of a Newfoundland

dog could transport yellow fever to a distant Mississippi town, and a newspaper printed in an Ohio village where smallpox was raging could fatally infect a United States consul in a foreign port where the disease did not exist, that a cloud of dust, a swarm of flies, or a single fly, as Sawtschenko, Simmonds, and Sternberg demonstrate, can disseminate cholera and become a focus of infection, which would have been impossible had ordinary care been exercised in preventing the exposure and promptly destroying the discharges and excreta of those already sick? Cities are reported clean whose sanitary inspectors have merely walked through crowded tenements, a hundred or more a day, and been satisfied with external evidences of brush and broom, leaving carpets and rugs unlifted; pieces of heavy furniture, with the fluff of years behind and beneath, unmoved; and closets, cupboards, pantries, storerooms, attics, and cellars undisturbed. The cellars of our great cities, and I speak with personal knowledge of many in New York, Brooklyn, and Philadelphia, are greater abominations than even filthy living apartments. The New York Herald of the 8th of August, narrating the death of two children by falling from a window on the fourth floor of a tenement at 204 West Sixty-first street, said:

To get at the bodies of her children the frantic mother had to go through the cellar of the house. There she waded through indescribable filth, almost knee-deep, to where her children lay, when the foul odors overcame her and she fainted.

It added:

The sanitary superintendent issued an order that the cellar must be cleaned out within twenty-four hours.

Do you believe that it was the only one of its kind that needed cleaning? No city can be accounted clean until its ordinances require every cellar door to be widely opened to sun and air, that royal pair of germicides; every cellar to be emptied of its refuse; every cellar wall and ceiling to be scraped and whitewashed; every cellar floor to be taken up if rotted, and sprinkled with lime if uncovered, a tedious and expensive process but effective sanitation, costly as it must need be, is cheap beside the outlay of a single epidemic. There are underground foulnesses in all our great cities of which they should be rid at any cost, as where ragpickers and bone gatherers collect their filthy stores and Italian street-corner fruit sellers keep their decomposing bananas, grapes, and oranges, till, rubbed off by dirty pocket handkerchiefs, they are exposed for sale, glistening after their repulsive polish with impure saliva. If some mote hunter, loath to see so huge a beam, chooses to find solace in disbelief, I might be able to shock him by declaring that I have seen the figs he munches unconcernedly flattened in their pretty boxes, in a country where syphilis reigns, by questionable thumbs moistened by equally suspicious saliva. Shall I, while revealing insanitary horrors, dare lift the sweeping train of the fair promenader, fashioned after that of women in other countries who never walk upon the streets, and show the nasty mess of spittle, excreta, mud, and dust she gathers from the sidewalks upon her white skirts and silk stockings? She will not believe me; but the bacteriologist who scoops the mud from between the cobblestones of the streets to find it swarming with microscopic life can gather as rich a harvest of microbes from these same dainty undergarments. Nor are these the only beams we overlook in our search for moles. Dr. Graham, bacteriologist of Starling Medical College, in response to an official inquiry by a member of Congress, reported that he was able to obtain thirteen colonies of two kinds of bacteria from one dirty, worn bank note, and the Medical Record of January 21 of this year states that a British bacteriologist discovered 19,000 microbes, including those of tuberculosis, diphtheria, and scarlatina, vegetating upon a single note. Other harborers of morbid germs are the textile fabrics employed in the furnishings of street cars and stages, which the chairman of the sanitary committee of the New

York board of health reports as "a menace to public health by reason of their continual exposure to uncleanness and infection from the clothing of diseased and filthy passengers," which, like their grimy bodies, may be foul with the sputa of diphtheria, tuberculosis, or syphilis, the desquamations of scarlatina, measles, or erysipelas, the emanations of typhus, or the alvine discharges of cholera or dysentery. A commendable league of zealous ladies, who are seeking to prevent the abominable practice of expectorating in public vehicles, induced a few car companies to display placards to the effect that "Gentlemen are requested not to spit on the floor," but these appeals, intended for beasts who were never gentlemen, were hung in inconspicuous places or covered by other notices, and the spitters continue to discharge their syphilitic and tubercular sputa on the floor mats, to be taken up on ladies' petticoats and carried to their homes. The spitter and the other beast who voids his impure nasal secretions where it suits him are largely responsible for the spread of influenza, for, according to Pfeiffer, the discoverer of its bacillus, "its contagium is found in the moist secretions of acute cases in the discharges from the nasal and bronchial mucous membranes."

Further detail would be out of place in an introductory address to this section. Let it suffice to point to the fragile spirillum of cholera which we are exorcising by "bell, book, and candle," as illustrating the dreaded *motes* of my text, and to the sturdy, robust bacillus of tubercle as the *beam* we will not consider. "Cholera," says Ernest Hart, "can only be drunk and eaten. It can not be caught and breathed;" but the tubercular mischief-maker, who finds the ever-open door of the respiratory passages his readiest approach, may also enter at any or all the orifices of the body. Among 1,000 autopsies, Osler found 275 with tuberculosis; among 8,873 patients in the surgical clinic at Würzburg, one-seventh (1,227) were tuberculous; the necroscopic statistics of Harris and others "show that one-third, perhaps over one-half, of the people who live to middle age have some form of tubercular infection;" and Dr. Williams, of Johns Hopkins Hospital, estimates that tuberculosis of the female generative organs is four times more frequent than generally supposed (Medical Record, March 18). Can any more obvious method of direct infection in these cases be imagined than the trailing skirts of women gathering tubercular sputa from the pavements?

The sanitary inspector is destined to become the most important agent of future civic administration. The perfunctory burning of a pan of sulphur in a diphtheritic chamber, the sprinkling here and there of a solution of corrosive sublimate, or the substitution of the sweeter scent of thymol, pinol, or some newer "ol" for the foul odor of the privy, will not then be the tolerated limit of his interference. All that science teaches and all that intelligence can devise will be exacted of him. A sanitary inspection will be a deliberate, painstaking, critical examination of nooks and corners and their disinfection, the flooding of the lairs of microscopic motes, and the deluging of unsightly beams with those unstopped, unpatented, inexhaustible germicides; air and sunshine.

Coincident with the approaching Eleventh International Medical Congress at Rome and its fitting complement there is to be an exposition of medicine and hygiene, and significant of the share accorded sanitary science in a medical congress representing the highest modern professional attainment, it will be noticed that of the ten classes which, in their *ensemble*, make up the exposition, five are exclusively hygienic, to wit, (4) plans, models, and *matériel* bearing on school management and sanitary civic organization (*riordinamento urbano*); (6) plans, models, and *matériel* for hygienic constructions; (7) apparatus and furniture for hygienic uses in the interior of common dwelling houses and public offices on every scale; (8) *matériel*, appliances, and accommodations for the practice of personal hygiene, and (9) plans, models, and appliances for the hygiene of the working classes. Three are partly hygienic, to wit, (1) apparatus, *matériel*, and plans of buildings

for scientific and technical investigation in therapeutics, biology, and hygiene; (3) articles and appurtenances requisite in salvage service and in *assistance publique*; and (10) books, atlases, photographs, and such like recently published and having reference to the medical, biologic, and hygienic sciences. Two only of the ten are exclusively medical and surgical, to wit, (2) apparatus, instruments, and *matériel thérapeutique* in the various departments of medicine, and (5) plans, apparatus, and furniture for the purposes of the divisional surgeon in cities. Additional to these, special classes are devoted to hydrology and balneo-therapy, and to the Italian Red Cross Society, both of which are practical outcomes of sanitary endeavor.

I do not forget that climatology and demography, as well as hygiene, are within the purview of this section; but what are climatology and climatotherapy but applied hygiene, and what is demography but the demonstration of the results of sanitary or insanitary conditions among masses of people? The climatologist is of necessity a hygiologist. The *materia medica* and *pharmacopœia* are not his text-books. Physical geography, meteorology, hydrology, balneology are his scriptures and gospels; the vivifying light, invigorating air, and healing springs and waters his armamenta—his anodynes and hypnotics, his roborants and eutrophics, his alterants and excernents. The high professional standing of the American Climatological Association, one of the constituent bodies of the Congress of American Physicians and Surgeons, and the distinguished climatologists who are with us to-day and who are conspicuous in every international congress of hygiene, are evidences of the place in medicine of climatotherapy, the practical end of medical climatology—that broad specialty which robs so many graves of untimely victims and makes so many, heretofore without hope, able, if not to take up their beds, at least to get out of them and walk. The field of the climatologist is as broad as the habitable surface of the globe—in the high altitudes of Colorado and the Alps; in the odorous pine forests of Norway and the Carolinas; on the seashore or upon the wide waste of waters and their islet oases swept by ocean breezes.

Our American vital statistics are not yet piled high enough to form the foundation for a substantial superstructure of demography. The great cauldron in which we are mixing Celts and Saxons, Semites and Aryans, with a seasoning of syphilis, tuberculosis, and insanity, is simmering with what ultimate homogeneity can only be conjectured. When immigration was a tiny stream, however muddy and noisome, poured into a rapid river of pure water, it was soon lost in the crystal fluid; but now that huge sewers are discharging their foetid pestilential torrents into a placid lake that has no outlet, the lake itself becomes turbid and unclean. Already in the *culs de sac*, which are nearest the open mouths of these foul sewers and receive their floating scum—the prisons, reformatories, almshouses, insane asylums, and hospitals—this filthy, debased, and diseased foreign element is ascendant, and our demographers have a simple task in representing its volume by numerical statistics. Dr. Frederick H. Wines, the distinguished compiler of this portion of the census of the United States for 1890, demonstrates by the indisputable evidence of figures that while the foreign born constitute only 17 per cent of our total white population—in round numbers about one-sixth—yet they furnish over half of all the paupers in the almshouses of the country. It is evident that the traits of the Saxon are disappearing from our national complexion, and if the proper solution of the negro question be, as suggested by certain prominent Afro-Americans, to bleach it out by admixture, we may expect the hue of our descendants to be decidedly tawny.

The most zealous demographers of this decade are the French, who have been spurred in their statistical researches to discover the causes of the too evident depopulation of France of its native races; but are we not again refusing to

consider the beam in our own eyes in not giving heed to the operation of similar conditions in our own country? Dr. Billings announces that our birth rate has fallen from 36 in 1,000 inhabitants in 1880 to 31 in 1,000 in 1890. The 20 to 30 children of our ancestors, the dozen or more of our great-grandmothers, have dwindled progressively to 5 or 6, then to 3 or 4, until to-day 1 or 2 or none represents the fecundity of the educated classes. The Independent, referring to New England Puritan life, says:

Large families abounded. According to Cotton Mather, one woman had 22 children and another 23 by one husband, and a third was mother to seven and twenty. Sir William Phipps was one of 26 children of the same mother. Printer Green had 30. The Rev. John Sherman, of Watertown, had 26 children by two wives, the second spouse the mother of 20. The Rev. Samuel Willard, first minister of Groton, had 20 children, being himself one of 17, as was Benjamin Franklin.

The paragraphist who can now record the case of the woman of 31, at Cold Spring, who has become the mother of 17 children in nine years, or that of the Georgia matron of 25 who rejoices in 13, has, in newspaper parlance, "a great find." The spectacle of impending maternity among our better classes is becoming more and more rare, and still more rare that of an infant nursing at its mother's breast. Only in the squalid quarters and *banlieues* of our great cities, where the English language is not spoken among imported lazzaroni and the overflow of European ghettos, does the process of human incubation go on as God and nature intended. The laws of creation are immutable, and one has only to look beneath the disfigurement of female dress to recognize the evidences of imperfect physical development—in stooping, unsymmetrical shoulders, in meager limbs, in narrow pelvises, and flattened busts.

Dr. Otis exhibited at the recent meeting of the American Climatological Association, in illustration of diametric measurements of the thorax, the profiles of a number of female chests, which were supposed to be those of little girls, until he explained that they were the contours of nubile young women in Boston normal schools, like her whom Solomon bewailed in the song of songs, "We have a little sister, and she hath no breasts. What shall we do for our little sister in the day when she shall be spoken for?" My friend Dr. Robert T. Morris, of New York, has significantly called attention to the fact that 80 per cent of all Aryan American women have rudimentary clitorides, and he asks if evolution is trying to do away with this organ in the degenerative changes characteristic of highly civilized varieties of the *Homo sapiens*, of which early falling hair, decaying teeth, weak mammary glands, and badly balanced eye muscles are other examples. Is the sexual instinct losing its potency as a maternal factor? Is marriage only a social office for the display of finery on the brides and bridesmaids and the entertainment of crowds of gaping strangers? Is the virgin wife best prepared for conception by months of preliminary surexcitation and feverish anxiety, and is a fatiguing railroad journey the best prelude to an act which should lead to the inception of a human being—the incarnation of a human soul? Has the function of reproduction come to be regarded only as a bestial and undesirable concomitant of matrimony and lactation its vulgar, indecent supplement, and is all this attributable to physical deterioration shown by the undeveloped or imprisoned *mentula muliebris* and atrophied mammae, and how far is this the explanation of the diminished fecundity of the Aryan American woman? These are problems as interesting to our demographers as the depopulation of France, the disappearance of South Sea Islanders, the migration of Semitic and Mongolian races, and the effects of malnutrition of indigenes of Ireland and Russia.

But, gentlemen, I shall no longer trench upon time that belongs to you. I am highly gratified at your presence, and thank you most cordially for your kind attention.

The remainder of the address was delivered in Spanish, of which the following is a translation :

GENTLEMEN, OUR FRIENDS AND COLLEAGUES FROM ABROAD: Permit me, on the part of the members of this section from the United States of America, to tender you a most hearty welcome to our capital. Your long travel to this city bespeaks your interest in the occasion. It is no light boast that here, for the first time in its history, the medical profession of all America finds itself united in one great congress. It was about nine years ago that a number of Canadian sanitarians claimed the right as Americans to become members of the American Public Health Association, and it was my privilege as president of that body to receive them as such. The subsequent transactions of that association show how loyal they have been to its traditions, how zealously they have participated in its work, and with what dignity they have filled its highest offices. Two years later they carried the association into their own territory at Toronto. In 1890 two distinguished representatives of the superior council of health of our sister Republic of Mexico came to Charleston and, as Americans, likewise knocked at the door of the American Public Health Association, returning the following year in such numbers and with such a hearty welcome from their Government to meet in their own capital that the invitation was accepted, and the most successful meeting of that association, the twentieth in its history, was held in the ancient city of the Toltecs. To-day the roll of States represented in the advisory council shows Illinois, Massachusetts, and Tennessee; Ontario, Quebec, and Manitoba; Guanajuato, Querétaro, and Zacatecas in one fraternal union. What sanitarians have done in that association, which bears the escutcheons of its three constituent countries side by side, this congress aims to accomplish for the whole profession of medicine in the Western Hemisphere, uniting its members in one brotherhood, whatever their race or language, and whether their homes be on the frozen shores of the Arctic or the hillsides of Terra del Fuego, among Greenland's icy mountains, in the archipelago of the West Indies, or amid the perennial gardens of Hawaii. Physicians and brothers from the United States of all America, welcome to this your capital, which, in that sweetest language spoken by human tongues, *ponemos á vuestra disposición*.

## PROCEEDINGS.

## FIRST SESSION.

TUESDAY, *September 5, 1893.*

The proceedings of the section were opened promptly by the president, Albert L. Gihon, medical director, United States Navy.

Dr. A. Nelson Bell, of Brooklyn, the senior honorary president of the section, then took the chair, while the president delivered his opening address.

On motion, the address was referred to the committee on publication.

Dr. Walter Wyman, Supervising Surgeon-General Marine-Hospital Service, being absent, the paper of Prof. Cornelius G. Comegys, of Cincinnati, Ohio, "On the proper status of the medical profession in the government of nations," was read.

After the reading of the paper, Dr. Atkinson, of Philadelphia, offered a resolution looking to the organization of a national department of health, which was seconded by Dr. Davis, of Philadelphia, and subsequently modified, with the mover's sanction, by the president, in the terms of his address, as follows:

*Resolved*, That in the opinion of the Section of Hygiene, Climatology, and Demography of the Pan-American Medical Congress the interests of the public health in every country should be and must be intrusted to a department of the Government especially charged with their administration, and that, while the precise form of administration may be left to legislation, the indispensable requisites are that it shall be national, that it shall have parity of voice and influence in the national council, that it shall have independent executive authority under the limitations common to other departments, and that it shall be intrusted to educated and experienced medical men, who alone are competent to assume its responsibilities.

Discussion on the resolution was opened by Dr. James F. Hibberd, of Richmond, Ind., president of the American Medical Association, who said: All the results of all activity in physics are the product of laws, God's laws; and we shall not be able to modify these results and direct them to the happiness of the human family until we study and understand these laws. Science is nothing more, nothing less, than an investigation of the laws of nature, and while we may stumble on knowledge that will be useful to us, the only way we can progress rapidly and profitably is to devote ourselves earnestly and continuously to scientific investigations. Much has been done by individual pursuit of science; more has been done by aggregations of people organized to further this investigation, and it must be an axiomatic proposition that the more persons and the more completely they are organized, and the better equipped with both power and means to push such investigations, the more speedy and the more valuable will be the results. Certainly in the United States there is no organization that approximates the power or the means of the Government itself to carry on these measures, and, consequently, there can be no question that it is the privilege, if not the duty, of this section to urge upon the Government of the United States to inaugurate an organization clothed with authority and supplied with means to make exhaustive cultivation of sanitary science and apply the result to the welfare and happiness of the people, which is the very highest function of government.

Dr. Felix Formento, of New Orleans, La., president of the State board of health of Louisiana, said: I suppose I am called upon by our honorable chairman because, in a spirit of justice and fairness, he wishes all the sides of the question to be presented. I can not indorse *in toto* the adoption of the resolution just presented. I am in favor of a bureau or department of health, provided the creation of this

bureau does not carry with it all the possible consequences implied and understood. As a delegate of the State of Louisiana and a representative of the Louisiana board of health I can hardly be expected to indorse such a resolution. I am in favor of a bureau of health the duties of which will be well defined. By means of the representatives of the Government abroad and the powerful means at their command it should be informed of the exact sanitary condition of every State in the Union and every country in the world, and keep all sanitary authorities in the United States fully informed of the same. It should gather vital statistics and make a thorough study, through its experts, of epidemic diseases, demography, etc. But it should not interfere in those States having a good system of quarantine and which have demonstrated by years of experience that they are fully able to protect themselves, and, in protecting themselves, protect the neighboring States. Louisiana, my native State, has fully demonstrated that she is entirely able to protect her citizens. She has the best system of quarantine in existence—a system which has been copied by the Federal Government and by other States. We have proved that yellow fever does not belong to our soil. It is a foreign disease, which an efficient system of quarantine will keep out of our country. For the last fourteen years yellow fever, which existed every year in our city, has not made its appearance in New Orleans, while there has not passed a single summer without cases of yellow fever occurring at our quarantine station. Louisiana has shown what she could do in this matter, and that without any assistance from the General Government. If each State protected itself as well, as it should do, there would be no necessity for any interference on the part of the Government. I am afraid that politics will greatly influence the formation of any such bureau. There might be possible discrimination between cities and cities, determined by commercial interests and influences. Besides, the same rules and regulations will not apply to all parts of the country. Those best qualified and able to protect themselves and their citizens are those who live and own all they possess in the threatened localities. I believe the Louisiana State board of health will better protect their people than any bureau in Washington. They are personally interested in this question. In addition to the scientific duties to be performed by it, this bureau of health might establish a standard which will govern the establishment of quarantine in those States which do not now have an efficient system. The resolution offered might go further than we wish to go.

Dr. John W. Trader, of Sedalia, Mo., said: I would like, Mr. Chairman, to have this resolution lay over until some hour on to-morrow. I would like to speak upon this subject, and, on account of the importance of the question, would like to have more time. I believe that we should have well-organized health laws that would have a uniform action over the whole country. To have a variety of laws enacted in the various States without a national uniformity would operate something like our divorce laws. What one State binds together another State divorces. We have had some experience in this clashing of authority. The fear expressed by some of establishing a Cabinet officer to preside over all sanitary matters in all the States can be removed by making this office appointive by the medical associations and scientific bodies, and not by Presidents or governors or judges who are not medical men. Whatever action is taken should look to a uniformity of all sanitary laws, operating alike in all States, cities, or municipalities.

Dr. S. F. Davis, president of the State board of health of Pennsylvania, said: Object lessons are used by the most notable educators to impress upon their pupils most readily and permanently important facts. I have no better argument to offer than to call your attention to the work done by Surg. Gen. Walter Wyman, of the Marine-Hospital Service. A better and more complete quarantine cordon could hardly be organized than now exists, showing, satisfactorily to my mind, that a national head, assisted by the various State boards, is the proper and only perfect plan to further the interest of preventive medicine.

Dr. Grant (Bey), of Cairo, Egypt, favored the idea of having the public health department represented in Congress. He said that England was feeling its way toward having a public health minister. For many years she has had a local government (sanitary) board which has furnished the information necessary to ministers ignorant of sanitary science when commercial and sanitary questions are on the carpet and laws dealing with these questions have to be passed. Much better would it be for ministers to have one of their number to guide them in these matters, and if the United States carries such a measure it will have dethroned England from the high position she now holds in all sanitary matters.

Dr. Charles O. Probst, of Columbus, Ohio, secretary of the State board of health of Ohio, said: Ohio desires to place herself on record as in favor of a national department of health. A resolution to this effect was adopted by our State board of health, which was indorsed by nearly every municipal board of health in the State. These resolutions were furnished to our members of Congress, and they were urged to support a bill for a national board of health. In establishing this department with a Cabinet officer at the head, we should keep in mind the fact that this officer will be subject to change every four years. This, in my judgment, makes it inadvisable to have its head in the Cabinet. Such an officer should be as little subject to political removal as possible.

Dr. Benjamin Lee, secretary of the State board of health of Pennsylvania, said: This question has been discussed from several points of view. It is a many-sided one. We have had it treated from the point of view of the traveller. I wish to say that, notwithstanding the perils depicted by one of the speakers, I propose to go home, and to do it without fear, and yet I am not sorry that my home is so near that I shall not be compelled to occupy that abomination, a sleeping car. On the kissing question I decline to commit myself too strongly. As regards seacoast quarantine, while there are, of course, objections on the part of those who are interested in local quarantine to any interference with their work on the part of the National Government, I am willing to say that for the sake of having a national health department, so far as the State board of health of Pennsylvania is concerned, we should be willing to be somewhat shorn of our own prerogatives. The question seems to be not, "Shall we have a national health authority?"—this we are all agreed would be desirable—but, "Shall this authority be a department or a board?" We have had a board and it has failed. From conditions of weakness inherent in itself it has fallen to pieces. Whether from local jealousies or outside influences it matters not. Now, let us try the other alternative and have a department, equal in power and respectability to any other Department of the Government.

Dr. Edward O. Shakespeare, of Philadelphia, Pa., said: I am in full accord with the broad principle expressed by this resolution, however I may doubt the policy at the present moment of recommending some details. Some of the objections raised by the representative of the Louisiana State board of health to national control of sanitation, it seems to me, are not founded upon a tenable basis. While local, municipal, and State governments have undoubtedly the inherent right to protect their own local territory against the causes of disease localized within their own limits, they have also equally the right to insist that their safety shall be secured against the dangers assailing from without. This is tantamount to denying the right of any municipality or State to so regulate or neglect to regulate its local sanitation in such a manner as that neighboring or even distant governments may be jeopardized. The State of Louisiana, fortunately for herself and for the whole country, has at the present time one of the most perfect sanitary organizations and establishments in the whole world so far as concerns quarantine against introduction of contagious disease by sea. But this gratifying state of affairs in Louisiana has not always existed. In fact, the present perfection and efficiency of the quar-

antine at New Orleans have sprung up within a few years, thanks to the wise, energetic labors of Dr. Holt, spurred on by the constant demands of the inhabitants of the whole Mississippi Valley beyond that State. I can not agree with the claim that no one outside of Louisiana, namely, the whole people of the United States, has a right to interfere with the right of that State in matters of quarantining. How the New Orleans quarantine is now regulated or may be in the future is something which this whole North American population has an inherent right to so supervise and control that whatever else may be done at the quarantine establishments at the mouth of the Mississippi, they shall, by their national laws, administered by their national officers, see to it that the rest of the country shall be efficiently and always protected. The operations of a national department of health need no more interfere with or abrogate the rights and duties of the State boards of health to effectively guard the citizens within the State than any department of the General Government now existing interferes with the local enactment and local administration of local laws or the existence of a national department of agriculture and a national department of law abrogates or interferes with the existence or functions of a State board of agriculture or of a State code of laws.

Dr. J. G. Hopkins, of Thomasville, Ga., said: As the representative of Georgia I wish to say that I think I voice the sentiment of that State when I say that I am in favor of this resolution. I blush to state that our legislative halls are annually filled with "hayseeds" who do not appreciate the importance of such; hence we have no State board of health. It is necessary that we have protection, and we think it but right that it come from the National Government.

Dr. Lawrence F. Flick, of Philadelphia, Pa., said: The question of sanitary science is a complicated one, and ought to be carefully studied before any practical measures are considered or recommended. The question implies legislation as well as execution. In our American system of government we have United States, State, city, and borough legislation. We accordingly ought to have United States, State, city, and borough executive officers. We must have legislation on medical matters not only in the United States but in States, cities, and boroughs, and we ought to have executive officers representing these various governments to enforce them. We should have a Cabinet officer for the United States, but we should also have State, city, and borough executive officers. The resolution recommends action on the part of the United States, which is a good beginning, and it ought to be adopted.

Dr. W. O. Daniel, of Georgia, said: I think we ought to have a national health department. In the absence of a State board of health in Georgia we have more than once been compelled to call upon the Federal Government to aid us in stamping out infectious and contagious diseases in Georgia. I think, too, that each State should control her department, except in general coast quarantine, as perhaps a standard that would be suitable for Pennsylvania would not be suitable for Louisiana. We are very proud of our State, but ashamed to acknowledge that we have no board of health. We are delighted, however, to be able to furnish to the United States the present Speaker of the House of Representatives. We hope soon to be able to thoroughly sanitize our State through the efforts of a State board of health.

Dr. L. P. Mullineux, of Astoria, Oreg., said: Sir, I favor this resolution because I believe it is the duty of this Government to care for the public health. If the people should care for the health of the country, it does not follow that the States will cease to care for its citizens. But, sir, it will strengthen the hands of the States, and where there is no State law it will be the cause of having law. Go, sir, to the Weather Bureau and see the detail work they have there. All parts of

the country are reached in a few hours. Then, sir, it will take the public health out of politics, and where they have trouble the Government will then have the power to settle all disputes. Now, sir, the health officers of almost all cities are the creatures of politics, and often, sir, they are unfit for the positions. Then, sir, we have parts of the country where State laws can not reach. I do hope, sir, that this section will favor this resolution.

Dr. J. S. Kelley, health commissioner, of Minneapolis, Minn., said: Representing, as I do, the great North Star State, the State of Minnesota, which is more interested in a national quarantine system than any other section of our country, receiving yearly thousands of immigrants, and located upon the great northern railroad systems carrying them farther into the interior, I therefore desire to be placed upon record as favoring the resolution.

Dr. William P. Lawler, of Lowell, Mass., said: I wish to add my approval to the resolution offered by the learned gentleman of Philadelphia. Much has been said about the importance of the preservation of public health. I will not dwell any longer on that point, but I look upon the establishment of a national department of health as a matter of real necessity. Under the present state of affairs there is always a danger of clashing between municipal boards of health and State sanitary commissions. In some States there are no boards of health; in others the rules and regulations are very meager and very imperfectly carried out. Now, by the establishment of a national health department we shall establish a body having such an executive authority that it will be able not only to arbitrate but dictate and command on all occasions where the public health and safety demand. The action of different departments of New York and the friction that occurred between them on the subject of quarantine are too recent to require any further mention. Some of the gentlemen who preceded me, and who appear to be a little conservative, seem to be inclined to regard this resolution as too radical. Well, Mr. Chairman, it is radical; and it is necessary that it should be radical. This subject has got to be treated from the very root. There is no half-way method about it. Let an epidemic of smallpox or yellow fever break out in one city or State and spread to a neighboring city or State, and no rules nor regulations can be mutually agreed upon between the health authorities of these respective localities; think of the irreparable losses that might follow while the conflicting sanitary officers would be parleying over questions of isolation, disinfection, and quarantine. The result is but too evident. The resolution now before the house does away with the possibility of any such peril. Another speaker is inclined to think that it would be inexpedient to bring such a sweeping resolution before Congress. Gentlemen, I hold that it is our duty to bring this question to a focus. It is our duty in congress here assembled to seek legislation on this subject, and to have laws passed that will cover the regulations of sanitation in all sections of the country. With yellow fever threatening us on the one side, and cholera staring us in the face on the other, I can not see how the National Government could disregard the appeal of this representative body. However, gentlemen, should Congress repudiate our request, then the responsibility will not be ours, and we shall have the consolation of knowing that we did our duty.

After the above discussion, Dr. Frederick Montizambert, of Quebec, Canada, honorary president of the section, being in the chair, Dr. Gihon offered the substitute as above given for the resolution of Dr. Atkinson, which was accepted by the latter and unanimously adopted by the section.

On adoption the resolution was referred to the congress in general session; was reported to the congress Wednesday, September 6, and referred to the international executive committee, and reported back approved, with instructions to communicate it to the executives of all the countries represented in the congress.

Dr. J. G. Hopkins, of Thomasville, Ga., moved the following resolution, seconded by Dr. Flick, of Philadelphia :

That it is the sense of this body that it is the duty of every State not already provided with exact laws providing for the establishment of a State board of health to provide the same.

Carried.

The following paper was then read : "Ojeada Retrospectiva Sobre la Organización de la Sanidad de los Ejércitos Españoles—Primeros Albores de la Medicina Militar en América," by Dr. Felix Estrada y Catoyra del Ejército de la Isla de Cuba.

The section adjourned.

---

## SECOND SESSION.

WEDNESDAY, *September 6, 1893.*

The meeting opened at 11:15 A. M., Dr. Frederick Montizambert, of Quebec, honorary president of the section, in the chair.

Dr. James Cecil Phillippo, of Kingston, Jamaica, British West Indies, read a paper on "The Climate, Hygiene, and Demography of Jamaica."

The paper by Dr. James H. Clarke, of Jamaica, on "The Climate of Santa Cruz Mountains" was thereafter read by title, and ordered to be printed.

Dr. Wolfred Nelson, of the city of New York, read a paper on "The Three Climates of Jamaica; its Coast or Tropical, Temperate, and Moderate Climates; Jamaica Regarded as a Winter Island for Health."

"Les Mesures Prophylactiques contre les Epidemies," by Dr. J. B. Lacerda, of Rio de Janeiro, Brazil, was read by title.

This was followed by Dr. Eduardo Liceaga, Presidente del Consejo Superior de Salubridad del Distrito Federal de México, on "Qué Bases Generales Podían Proponerse á los Diversos Gobiernos del Continente Americano Para Hacer Uniforme y Eficáz la Policia Sanitaria Marítima Internacional."

Dr. J. A. S. Grant (Bey), of Cairo, Egypt, read a paper on "The Climate of Egypt in Geological, Prehistoric, and Ancient Historic Times."

The paper by John C. Sundberg, consul for the United States of America at Bagdad, Asiatic Turkey, on "The Climatology and Demography of Mesopotamia" was read by title, and ordered to be printed, as were also the following : "Hygiene de Monterey" by Dr. Fermín Martinez, Monterey, México ; "Apuntes Sobre la Patología del Departamento Fluvial de Loreto," by Dr. Leónidas Avendano, Lima, Perú.

The section then adjourned.

---

## THIRD SESSION.

WEDNESDAY, *September 6, 1893.*

The section met at 3 P. M., the president in the chair.

Dr. George Homan, commissioner of health of St. Louis, Mo., read a paper on "Municipal Sanitation in St. Louis." It was followed by a paper by Dr. Domingo Orvañanos, secretary of the superior board of health of Mexico, on "Causas y Modos de la Propagación de la Neumonía Lobar Aguda."

Discussion on the papers already read being opened, Dr. John H. Rauch, Illinois, presented a resolution recommending that on account of Asiatic cholera in Europe immigration be restricted.

Discussion on the resolution took place and was participated in by Dr. James A. Stewart, health officer of Baltimore; Dr. Shakespeare, Philadelphia; Dr. Kelley, of Minneapolis, Minn., and others. Amongst these:

Dr. Lee, secretary State board of health of Pennsylvania, Philadelphia, said: I desire to go on record as in favor of restricting immigration from places or ports in which cholera prevails. At the same time it occurs to me that the resolution needs modification. We should specify a little more definitely what we mean by the prevalence of cholera. Shall we say that because during the past two weeks there have been several cases of cholera in England cholera is prevalent in that country, and we shall therefore suspend immigration from Great Britain? Further, the resolution is based upon economic as well as sanitary grounds. Now, I take it that neither this section of hygiene, nor the congress of which it forms a part, has anything to do with economic questions. Whatever we may think as individuals as to the expediency of limiting immigration, from a financial standpoint, especially during our present perturbed condition commercially, we as a sanitary body should be going entirely out of our province in making suggestions on that ground.

Dr. Lawrence F. Flick, Philadelphia, said: The resolution as offered is objectionable for the two reasons called attention to by Dr. Lee. The principle employed, however, namely, that immigration from countries in which cholera prevails should be stopped, will meet with the approval of all. We might adopt the resolution so amended as to leave out the objectionable features.

Dr. Cyrus Edson, commissioner of health of the city of New York, said: I hope this resolution will receive the indorsement of this section and of the Pan-American Medical Congress. I believe that an expression of opinion on the subject in question, in the manner that this is expressed, will certainly result in stoppage of a traffic that is in the highest degree dangerous to the well being of the various countries represented in this gathering. In my opinion it is not possible to maintain a quarantine against Asiatic cholera that will be certain and sure of successful results. I say this with all respect and deference to my colleague, Dr. Jenkins, the health officer of the port of New York, who, I know, does not agree with my opinion. I believe, and no one has had closer opportunity for forming judgment, that Dr. Jenkins's quarantine is as ably administered as that of any other port in the world. His work this year in connection with the cholera steamship *Karamania* is worthy of our highest commendation; nevertheless, neither Dr. Jenkins nor any other man can to a certainty keep cholera out of this country when the disease is on shipboard within one of our ports. Our experience of last year has led me, and it must also lead others, to this conclusion. Last year cholera appeared in the lower bay of New York Harbor, and within fourteen days nine authenticated cases of the disease were in the city of New York. This year, following the arrival of a cholera-infected ship, a case declared to be cholera by such men as Biggs, Kinyoun, Park, and Prudden appears in Jersey City. I believe that the disease in these instances can be accounted for in only one way, and that is through the medium of fly infection. Careful experiments have proven that the house fly can carry on his feet and in his body the spirillum of cholera, and that the spirilli thus carried will remain active for several days. A fly is a most rapid flyer, and can traverse the entire length of Manhattan Island within fifteen minutes. A fly may infect itself by contact with cholera dejecta in the lower bay and carry his load to a fertile soil in the heart of the city within a short time. I believe in this theory of fly infection, because it has been proven; believing it, I can not believe that cholera can be successfully quarantined. The temporary stoppage of emigration from infected countries will work no harm to any interests at this time except those of the steamship companies. It is the safest and best course for the welfare of the many. We may not be able to agree upon the ground of expe-

diency or science in this matter, but there can be no two opinions concerning the efficiency of the proposition to the end that cholera be kept out. The consequences that will follow should it gain a foothold in our small towns will be so disastrous that if we err at all in our fight against it, our mistake should be on the side of public safety. It has been said that this measure is a political one, and that it has no place in a scientific gathering of the character of the Pan-American Medical Congress. This is not the view for us to take. Science, religion, and politics are to-day so closely interlocked that they can not be considered separately. The section on hygiene is the connecting link between the Pan-American Medical Congress and the body politic. We hygienists are and must be in touch with public questions that affect the lives and health of communities. We must be in the highest sense of the word politicians. If you refuse to consider this great public question through fear of politics, then your fear of politics should lead you to banish public hygiene from the sections of your congress.

After a very full discussion the resolution of Dr. Rauch, amended by a committee appointed by the president and consisting of Dr. Edson, New York; Dr. Shakespeare, Philadelphia; and Dr. Lee, Philadelphia, was unanimously adopted by the section.

The resolution is as follows :

*Resolved*, That it is the sense of the section on hygiene, climatology, and demography that in view of the prevalence of Asiatic cholera in Europe at the present time and the constantly increasing number of foci of infection, immigration from European countries in which cholera exists should be temporarily suspended, as this action affords, in our opinion, the only certain means of averting a threatened invasion of the disease of the countries of the American continent.

*Be it further resolved*, That this resolution be reported to the general session of the Pan-American Medical Congress with a request for its adoption and speedy transmittal to the executives of the several countries officially represented therein.

It was further moved by Dr. Ruggles, president of the State board of health of California, seconded by Dr. Flick, of Philadelphia, and resolved by the section on hygiene, climatology, and demography that "the Congress of the United States of America be most earnestly requested to cause a large edition of the very valuable report of Dr. Edward O. Shakespeare, of Philadelphia, of his researches in cholera to be printed for distribution among the several countries represented in the Pan-American Medical Congress."

Carried.

Dr. James M. Postle, Hinckley, Ill., then read a paper "On the Need of Research in Preventive Medicine." This was followed by a paper "On Schools in Relation to the Spread of Diphtheria," by Peter H. Bryce, M. A., M. D., of Toronto, secretary provincial board of health of Ontario, Canada.

The meeting then adjourned.

---

#### FOURTH SESSION.

THURSDAY, September 7, 1893.

The section met at 11 A. M., the president in the chair.

A paper was read by Dr. Jesús E. Monjarás, of San Luis Potosí, Mexico, entitled "Medidas que Deben Tomarse para Impedir el Desarrollo de las Enfermedades Transmisibles en las Ciudades."

The next paper which was read by title was "On the Early Detection of Phthisis, Including the Author's Contributions to Diagnostic Means; with a few Considerations of a Possible Pretubercular Stage," by Charles Denison, A. M., M. D., of Denver, Colo.

Thereafter Dr. Lawrence F. Flick, of Philadelphia, Pa., read a paper "On Practical Measures for the Prevention of Tuberculosis."

A paper by K. von Ruck, Asheville, N. C., on "The Climate of Western North Carolina, with a Consideration of the Relative Values of High and Medium Altitudes on the Treatment of Pulmonary Tuberculosis," was read by title. This was followed by a paper by Dr. G. Farrar Patton, New Orleans, La., on "Suggestions for a Plan to Enable the Masters of Merchant Vessels to Properly Care for Those Attacked at Sea with Yellow Fever," and by a paper "On Isthmian Practices with Regard to Burial of Dead," by Dr. Wolfred Nelson, of New York.

Dr. Juan J. Ulloa, of Costa Rica, read a paper on "Observations on the Convenience of Establishing a Uniform American International System of Quarantine and American Hygiene."

The following resolution was then adopted:

*Resolved*, That the Pan-American Medical Congress considers of the utmost importance as great a uniformity as practicable of laws and regulations concerning maritime hygiene and quarantine for all countries of America; and hopes that the United States Government will initiate a movement in this direction by calling a meeting at some early date of delegates sufficiently authorized by the several American countries, whose object would be the study of the whole question of maritime hygiene and quarantine, as well as international sanitation as they are especially related to the conditions prevailing over the American Hemisphere and adjacent isles.

*Resolved*, That the foregoing resolution be reported to the general session of the Pan-American Medical Congress, with a request for its adoption, and, in such case, thereafter transmitted to the executives of the several countries represented in this congress.

Dr. Benjamin Lee, of Philadelphia, secretary State board of health, Pennsylvania, then read a paper entitled "Does the Presence of Leprosy in the United States of America, Canada, and Mexico Call for the Supervision of their Several Federal Governments?"

The session then adjourned.

---

## FIFTH SESSION.

THURSDAY, *September 7, 1893.*

The section met at 3 P. M., Dr. Formento, of New Orleans, honorary president, in the chair.

A paper was read by Dr. Beaven Rake, medical superintendent of the Leper Asylum, island of Trinidad, British West Indies, late member of the Indian Leprosy Commission, "On the Communicability of leprosy."

A discussion on these papers was participated in by Dr. Nelson, of New York; Dr. Shakespeare, of Philadelphia, and Dr. Carter.

Dr. Lee replied in the discussion and moved the following resolution, which was lost:

*Resolved*, That it is the sense of the section on hygiene, climatology, and demography that the prevalence of leprosy in British America, the United States of America, and the Republic of Mexico is such as to make it a proper subject for the attention of the federal governments of these countries.

*Resolved*, That this resolution be transmitted to the general session of the congress for its consideration.

The following papers were then presented by Dr. Prosper de Pietra Santa, de St. Cloud, France, Rédacteur du Journal D'Hygiene de Paris, on "L'eau de Seltz à Paris—Historique du Siphon—Gazéification par l'Acide Carbonique Liquide;" and on "El Bocio en la America del Sud," by Dr. Samuel Gache, of Buenos Ayres, Republica Argentina.

The following resolution, moved by Dr. Charles A. Probst, secretary of the State board of health of Ohio, seconded by Dr. Ruggles, president of the State board of health of California, was offered:

*Resolved*, That it is the belief of the section on hygiene, climatology, and demography that owing to the facts (1) that tuberculosis causes more deaths than any other disease; (2) that it is now known to be communicable, especially to persons living in houses and shops with consumptives, that the attention of national, State, and municipal authorities be directed to the necessity for controlling the dissemination of the disease by (1) notification by physicians and householders; (2) regulation of the residences of the tuberculized; (3) controlling, as far as necessary, their movements; (4) establishing of hospitals and homes for the infected poor.

Discussion on the resolution, which was finally adopted, was carried on by the following:

Dr. J. G. Hopkins, of Thomasville, Ga., said: Now that my object has been accomplished, I rise to explain my purpose in opposing the adoption of the resolution. It was to induce discussion upon a resolution on a subject of vital importance, which seemed clear to my mind was about to pass with a word. Now that that object has been accomplished, I arise to say that I am in favor of it except so far as it applies to hospitals. I am in full sympathy with the gentleman who proposed the resolution. I have been upon that platform a long time, and I believe those who are not are persons who have not investigated the subject with sufficient thoroughness. I oppose hospitals for consumptives or crowding them in any manner. The proper manner to dispose of them would be to isolate them in the cottage system. What I might say further would be but repetition and do violence to the intelligence of this congress, as most that has been said in this discussion so far is embodied in an article I read before the Georgia Medical Association last May, and published in the Journal of the American Medical Association in July, and of course has been read by you all.

Dr. Peter D. Keyser, of Philadelphia, Pa., said: I rise to sustain the resolution as presented in relation to tuberculosis, and say that it is necessary to educate the mass of the people by compulsion in the matter of prevention of contagious diseases. The great body of the people do not really think in these matters, but are governed by ignorance as well as sympathy. Many do not read any circulars that may be sent by the health officer to the houses; others can not read, and therefore take no notice of the same; and therefore for their benefit, as well as for the benefit of the people, is it necessary to educate in this matter compulsorily. I therefore hope that the resolution will be adopted. Many people will do nothing except under law, and therefore if a law to regulate this question of tuberculosis be adopted it will be respected and this disease no doubt abated.

Dr. William E. Driscoll, of Muncie, Ind., said: I differ from the gentleman from Oregon. It is far from my purpose to impute to any gentleman or lady in this presence that they are tainted with syphilis, and I do feel sure that everyone present is in danger of contracting consumption. There has not been a day since we began to live that all of us have not breathed into our lungs the seeds of this dreadful disease; and the only reason we are not suffering from consumption to-day is because we have not furnished a suitable soil for the lodgment and growth of these germs. We are in danger at all times, especially when brought repeatedly in close proximity to this infection. Of course syphilis, scrofula, and kindred diseases render the subject more easily infected and less powerful to resist this disease. It is folly to claim that syphilis is intimately connected with this disease any more than fever, pneumonia, or any other malady. I am in favor of educating the people and legislating on this subject. It is time we were taking national and State legislative steps in the direction of removing the danger to the uninfected.

Dr. Lawrence F. Flick, of Philadelphia, Pa., said: I wish to set the discussion right in a few things that it has gone wrong in. The resolutions do not contemplate enacting law. The boards of health have power to place a disease on the list of returnable diseases. The recommendation of the establishment of hospitals is simply recommending a measure to our Government for consideration. Two statements I wish to protest against. First, that there is any relation between syphilis and tuberculosis. No one acquainted with the facts would make such a statement at present. Secondly, that we inhale tubercle bacilli all the time and everywhere. This erroneous idea has done more harm and has done more to prevent the progress of preventive medicine than aught that has ever been said and done. I would say in connection with this matter that very few of us have probably inhaled tubercle bacilli. It requires special environment to convey tuberculosis. It requires exposures by social relations, and continued exposure, to contract the disease. No man, no matter what history of heredity he may have, what his physical condition may be, or how moral he may be, will withstand exposure to tuberculosis if the exposure is great and long enough.

Dr. William Tillman, of La Crosse, Wis., said: The resolution is good and if enforced will be a blessing to the country. I am afraid, however, that the public will fight against it for two reasons. In the first place, the public will not understand why such rigorous laws should be enacted, because they do not know that tuberculosis is contagious. Secondly, the public, and even our Government, will probably not be in favor of these laws, as the expense of disinfection, if carried out successfully, will be very great. In many instances it will be necessary not to disinfect but to destroy property (even houses). The public will surely fight this, and the Government will have to bear all the expenses. If these objections to this resolution could be overcome, I believe that the enforcement of these laws would be followed by the best of results.

Dr. Charles A. Lindsley, of New Haven, Conn., secretary of the State board of health of Connecticut, said that he thought the present discussion was one of the most profitable that he had listened to; that we would all go back to our homes with acquired information derived from this very instructive exchange of opinions. But there appears to be a remarkable persistence in misunderstanding the purport of the resolution under discussion. Gentlemen insist upon debating the expediency of legislating upon the means of controlling the spread of this disease. The resolution, as I remember it, does not call for legislation, but simply directs attention of State and local boards of health to the practical means of restricting the disease, to be used in the best manner that their discretion and powers may indicate. Dr. Bell has very emphatically insisted upon the registration of all deaths from tuberculosis. That is a very essential thing to do. But mere registration of such events, it is quite evident, is not sufficient, because in Massachusetts, Connecticut, Rhode Island, and many other States such registration has been practiced for many years without perceptible abatement of the disease. Something more than that is necessary.

Dr. Bell said the cases must be followed up.

Dr. Lindsley said: Yes, sir; that is the point exactly, and, to my mind, is just exactly what this resolution aims at—to have the State and local health authorities follow up such cases, guided by the present light of science upon the subject. I fully agree in all that has been said about educating the public, and I regard the operation of this resolution an important factor in such educational process.

Dr. William P. Lawler, of Lowell, Mass., said: Before putting the question to the house I wish to add my approbation to the resolution in its original form without any alteration or any further amending. It seems to me that some of the members are laying too much stress on the subject of law, which in reality does not exist in the resolution. By the passage of the resolution we do not bind

ourselves down by any legal obligations. The importance of this subject can not be overestimated. When we consider the terrible death rate that prevails in our midst year after year from the tubercle bacillus, we can not, in duty bound, sit here in silence and allow this resolution to pass unnoticed. From my earliest boyhood I can readily call to mind whole families that have been swept away by this deadly enemy. On looking back to my college days I see some of the strongest and most perfect specimens of physical manhood fall victims to this unseen foe in the very prime and vigor of life. And in our own daily experience, gentlemen, in the practice of our profession, do we not witness the fairest and most beautiful of the human family sink into early graves from the very same cause, when youth, wealth, and medical skill prove to be of no avail? These are cold, hard facts, gentlemen, that can not be overlooked. But thanks to the recent discoveries and developments that have been made in regard to the pathology of tuberculosis, we have within our power, in the way of prophylaxis, more effectual means with which to combat this mortal disease, and, fortunately, we can see much brighter days in store for the whole human race. Gentlemen, there is no other disease about which the people at large are so densely ignorant, and at the same time so sadly negligent, as tuberculosis. Even many physicians, I am sorry to say, do not give it the attention that their duty requires. But the time has come, gentlemen, when the medical profession of the present day has got upon its hands a duty to perform that can be accomplished only by constant zeal and harmony of action. The substance of this resolution is only the beginning of a series of more stupendous and radical enactments that must necessarily follow from it; but it will establish a criterion on which we can act, and at the same time serve as a guide to medical and scientific associations that can develop it more fully in the not far distant future.

Dr. Peter H. Bryce, of Toronto, Canada, said that the statistics which he quoted seemed to him to be sufficient reason for urging the passage of such a resolution by the section. These figures showed its constant distribution in families, and hence attending physicians who have diagnosed the disease would report cases in order that the health authorities may aid them in further regulations of the sick. In the case of careless physicians, it is more desirable that the local boards of health have knowledge of cases in order that they may enforce sanitary regulations, and the facts referred to in the president's address on the danger to travellers from tuberculized travellers in the common apartments of railways and steamboats, indicate the absolute necessity for national and State attention to the making of special provision for the carriage of tuberculized persons to sanitariums, etc., while the presence of the tuberculized in work rooms, etc., demands that the regulation of this class be enforced, and in order that no hardship occur, it is desirable that the hospitals and homes to which they can go be established.

Dr. G. F. Patton, vice-president of the Louisiana State board of health and chairman of quarantine committee, moved the following resolution, which was seconded by Dr. Hopkins, of Georgia:

Whereas it is known that many of those stricken with yellow fever on merchant vessels at sea die from want of proper care and treatment at the hands of the masters of such vessels,

*Be it resolved*, That this section, impressed with the wide scope and humanitarian objects of the work undertaken by the Pan-American Medical Congress, hereby recommends that this congress shall ask of the various governments therein represented, and of all enlightened nations, that it be made part of the duty of consuls at ports infected with yellow fever to furnish every shipmaster clearing from such ports with a printed memorandum of instructions, to be issued by competent medical authority under Government supervision, and setting forth in simple language the principal points as to diagnosis, nursing, and treatment; these instructions to make it incumbent upon every such shipmaster to provide his vessel with a clinical thermometer, and with such articles of diet, stimulants, and medicines as may be therein specified.

The paper of Dr. John C. Wise, surgeon, U. S. Navy, entitled "A Brief Consideration of Elephantiasis Arabum as Observed in the Samoan Islands," was read by title. Also the paper by Medical Inspector George W. Woods, U. S. Navy, "On Some Peculiar Diseases Encountered in Naval Cruising, and Recent Observations on Hawaiian Leprosy."

The section then adjourned.

### THE SIXTH SESSION.

FRIDAY, *September 8, 1893.*

The section met at 9 A. M., the president in the chair.

A paper entitled "On Pestilential Conditions," was read by Dr. A. Nelson Bell, of Brooklyn, N. Y., editor of *The Sanitarian*. This was followed by a paper entitled "Responsibility for Spreading Disease," by Dr. Wolfred Nelson, of New York City.

Dr. Edward O. Shakespeare, of Philadelphia, Pa., thereafter offered the following resolutions, which, after discussion by Dr. Carter, U. S. Marine-Hospital Service; Dr. Austin, U. S. Marine-Hospital Service; Dr. Thomas S. Scales, Mobile, Ala.; Dr. Charles O. Probst, Columbus, Ohio; Dr. Henry B. Baker, Lansing, Mich.; Dr. G. Farrar Patton, New Orleans, La.; Dr. Elijah S. Kelley, Minneapolis, Minn., were unanimously adopted and directed to be referred to the congress in general session:

*Resolved*, That the following resolutions be added to the resolutions already adopted and reported to the general session, relative to temporary suspension of immigration, to wit:

*Resolved*, That in the opinion of this section the thorough disinfection, without discrimination, of every piece of baggage, dunnage, or article of personal effects belonging to the immigrant classes and to crews of immigrant ships, and the exaction of scrupulous cleanliness of all vessels arriving at Pan-American ports should be rigidly enforced at American ports, supplementing and enhancing the protective value of similar treatment at the ports of departure, especially at times when cholera exists in Europe, as a sanitary precaution, second only in efficiency and importance to the temporary suspension of immigration.

*Resolved*, That it is also the opinion of this section that the habitual and thorough disinfection of all personal effects liable to carry contagion of immigrants to the American Hemisphere, and of dunnage of crews of vessels carrying immigrants from any quarter of the globe, and the exaction of scrupulous cleanliness of all vessels arriving at American ports should be enforced at all times as the most efficient means of greatly lessening the introduction into this hemisphere of the seeds of various contagious diseases, which are now and have been in the past almost constantly conveyed by the immigrant classes and distributed widely among the population of this hemisphere.

Among other remarks, Dr. Bell said, with reference to Dr. Nelson's characterization of an ideal quarantine, that, in his judgment, an ideal quarantine is that which implies the maintenance of such scrupulous cleanliness at the port of arrival as to require no quarantine except the exaction of equally scrupulous cleanliness of all vessels, merchandise, persons, and personal baggage purposing to enter such port.

A paper was thereafter read "On Demographic Statistics of Disease in the State of Michigan for Fifteen Years Consecutively," by Dr. Henry B. Baker, secretary of the State board of health of Michigan.

Dr. Charles A. Ruggles, president of the State board of health of California, opened a discussion on the subject of the prevention of the spread of diphtheria, which was participated in by Dr. A. Nelson Bell, of New York; Dr. A. B. Baker, of Michigan; Dr. John S. Arwine, of Indiana; Dr. Lewis, of North Carolina; and Dr. Samuel Garlick, of Connecticut.

Dr. Arwine, of Columbus, Ind., said: I regard the paper on diphtheria an able résumé of the consensus of medical opinion. As I understand it, the majority of

the profession entertain the opinion that Loeffler's bacillus is the specific cause of the disease. If my memory serves me correctly, some observers claim the presence of the bacillus necessary to establish the identity of diphtheria. This may be the true theory, but I am not prepared to accept it as such. I am of the opinion diphtheria is the result of a specific poison more subtle and dangerous to human life than the bacillus, though not recognized. It operates upon those who come in contact with it insidiously, causing them to become weak and anemic with irritable fauces, whose mucous membranes are denuded of much epithelium by the action of this subtle poison, which has prepared the fauces to throw out the diphtheritic deposit, probably nature's effort to repair the mucous membrane; but as the system is poisoned or depraved, nature fails, and the exudate forms a nidus for the bacillus, which is secondary and in no way causative. The inhabitants of that beautiful little city, Columbus, Ind., which I have the honor to represent, quite recently experienced an endemic of diphtheria, which hovered over the city from June, 1892, to January, 1893. The outbreak occurred in a tenement located on a low lot, where the ground water stood from 3 to 5 feet below the surface. Storm water frequently forms a pond on the back lot. Consequently the hygienic condition of the place is bad, and as there was no suspicious case to refer to as the possible cause of the outbreak, it is quite probable the poison causing it was generated on the lot, or in the tenement, where it became a focus that spread among the people, increasing in virulence until in September there were reported 60 cases; October, 40; November, 50; December, 10—a total of 160 cases, of which 30 died. It is probable that nine-tenths of those who suffered with the disease were occupants of tenements where the hygienic surroundings were anything but good. (Landlords with us are not noted for making hygienic improvements for their tenantry.) While this is true, I must not omit mentioning the fact that quarantining was neither enforced nor observed as it should have been; consequently the disease lingered with us. To sustain the idea of diphtheria being due to a subtle poison, I will mention the fact that some six or eight weeks since an outbreak occurred some 25 miles southwest of Columbus, Ind., in a sparsely settled, broken district, some 15 or 20 miles from railways, through which no well-used thoroughfare passes. In this neighborhood most of the dwellings are found along the narrow valleys of the small streams on the foothills. The inhabitants obtain water for family use from shallow wells, which yield surface water and shale scrapings; the hills being underlaid with blue shale, which is covered with sandstone and clay. The streams in this part of the country are, in the latter part of summer, usually found to contain no water save an occasional pool, about which stock gather, causing them to become quite filthy, and in case of extreme drought, such as is now upon us, one can better imagine the character of the water drawn from the shallow wells than describe it. Certainly it can be nothing but the scraping from cesspools and shale beds surcharged with mineral, vegetable, and animal poisons of sufficient virulence to destroy the nutrition of those who habitually use it. I imagine the continued use of water thus drugged will not only destroy nutrition, but irritate the fauces, destroy much of the epithelium of the mucous membrane, which causes them to throw out a deposit that frequently becomes diphtheritic, with all its attendant consequences. As the aforementioned outbreak could be referred to no suspicious case, there is every reason to believe it sprang from the poisoned water. I know of no reason that can be adduced why a disease thus started may not assume the form of a contagion or infection and spread as such among those who are exposed to the action of the same or a similar poison.

Dr. William P. Lawler, city physician of Lowell, Mass., said: The report of Dr. Baker on the summary statement of the Michigan State board of health, containing as it does such thorough yet simple diagrams and tables, are so complete in all its details that I consider it the duty of this section to confer upon the honorable

gentleman of the Northwest a unanimous vote of thanks and an expression of our sincere congratulations. The matter and form of this report are so replete with practical information, all tabulated before the eye in the simplest manner possible, that I regard it as a document of much value. Without going into any discussion as to whether diphtheria, primarily, is a local or a constitutional disease, it can not be denied, from the numerous recent experiments and microscopic examinations of pathologists, that there are many cases in which the origin of this disease is purely local. We know that diphtheria is extremely contagious; we know that it is preëminently a disease of childhood, and, ever bearing these facts in mind, we can not attach too much importance to its prophylaxis. Prevention is always easier than cure. This rule holds good in all diseases, and in diphtheria it is but too clearly demonstrated. The physician in these cases can not act alone. He requires the coöperation of the local and State authorities. And, here, gentlemen, comes in the duty of local boards of health. In the city of Lowell, Mass., which, by the way, I have the honor of representing at this congress, the board of health has done much during the past few years in curtailing the spreading of diphtheria and other contagious diseases. In our city every physician is required by law to report to the board of health each and every case of contagious disease as soon as discovered. An officer of the health department is immediately sent to the infected premises, and the house is placarded. A printed pamphlet is given to the inmates of the house describing the danger of the contagion and the grave necessity of isolation and disinfection. The disinfection is always conducted by a health officer. Notice of the disease is also immediately sent to the school board so that no children living in the infected house will be permitted to go to school until the danger of contagion has passed. The importance of thorough cleanliness, good ventilation, and plenty of sunlight is ever kept before the minds of the people in all cases where contagious disease exists. Gentlemen, when every man, woman, and child can be convinced of the importance of isolation and disinfection in all contagious diseases; when each and every man can be brought to realize the fact that it is his conscientious duty toward his neighbor, his city, and his country to do all in his power to prevent the propagation of these deadly diseases, and that he will exercise this duty by prohibiting any of his family, whenever there is a case of contagious disease in his household, to enter a school, church, public library, theater, ballroom, railroad station, or any public conveyance—then, gentlemen, when that time comes, when every citizen becomes a sanitarian, we can look for a remarkable abatement of diphtheria and all other contagious diseases, far greater, indeed, than the combined action of all the drugs and medicines contained in the pharmacopœia.

A discussion on the subject of the identification of immigrants and their baggage after examination and disinfection in transport to other localities was opened by Dr. Henry B. Baker, of Michigan, and participated in by Dr. Montizambert, of Quebec; Dr. Austin, of the U. S. Marine-Hospital Service, and Dr. Elijah S. Kelley, the commissioner of health of Minneapolis, Minn., the latter gentleman warmly commending and indorsing the system in practice at the Grosse Isle Station on the St. Lawrence River, near Quebec, under the superintendence of Dr. Montizambert.

Dr. Kelley said: During the cholera scare of 1892 I had the honor of being a representative of the great State of Minnesota, sent to investigate the processes of fumigation and disinfection in active operation at the various quarantine stations upon our Atlantic coast. At Sault Ste. Marie we investigated the quarantine system adopted by the State board of Michigan and the apparatus for disinfection of immigrants, baggage, and clothing. This consisted of a box car, side-tracked, connected with a stationary engine by 100 feet of rubber garden hose, running under the iron rails or tracks. The clothing of the immigrants

was hung on wire ropes inside this car and the steam admitted through an opening in the bottom of the car. The steam, passing through the hose, became cooled to such an extent that the clothing in the car was simply saturated with moisture and was far below any temperature calculated to destroy bacilli of any kind. In my opinion, it was better adapted for the prolific generation of bacilli, and markedly inferior to sunlight and air as a germicide. What prompted such a travesty upon the intelligence of our citizens can perhaps be explained by Dr. Baker, of Michigan. Twenty-seven immigrants detained for twenty days without water-closet accommodations, the faecal deposits accumulating beneath the car in which they were kept; no means afforded for cooking food or for bathing. In many instances the immigrants wandered all over the city without restraint. This was a condition of affairs as inhuman and barbarous as the culpable ignorance which prompted it. In Boston we were royally entertained. We were taken down the harbor to an island which nature had provided for quarantine purposes. Hospitals for contagious diseases were ample, but the apparatus for the disinfection of immigrants was a farce. A box made of rough boards, 7 feet wide, 8 feet high, and 10 feet long, with a door and hole in the side for the introduction of a rubber hose to convey the steam from the steamer, was the whole quarantine outfit for fumigation and disinfecting in sight. That very morning immigrants from questionable points in Europe had passed through Boston Quarantine, destined for the Northwest, and in Boston Harbor were two vessels, one loaded with beet sugar in sacks, direct from Hamburg for Boston sugar refineries, the other loaded with baled rags, direct from cholera-infected regions of Europe. Let silence on my part express the feeling of indignation which words can not, as to the inefficiency of such a quarantine and its protection to the people of Minnesota. Our visit to Grosse Isle, Quebec, Canada, was a surprise. There we found a quarantine in reality and a health officer discharging his duties manfully to his own country and the whole Northwest. A boat specially fitted with sulphur apparatus and corrosive-sublimate solution for the disinfection of the vessels, a sterilizer of larger size was in operation, where clothing could be readily placed in this iron cylinder and air exhausted, then steam heated to 230° admitted, insuring certain destruction to any form of bacillus. Detention hospitals, cooking establishments, bathing rooms, water-closets, for male and female, wash rooms, police patrol, and ambulances for the removal of the sick. Telegrams warned the officer in charge hours before infected vessels reached the quarantine line. The ashes of cholera-infected baled rags whitened the rocks and the smoke darkened the air above them, while military exactness, honesty of purpose, and intelligent work everywhere indicated that a master mind familiar with every detail and phase of quarantine service, directs and controls, and deserves the gratitude of the whole Northwest.

The following papers were read by title: "Movimiento Demográfico de Buenos Aires," by Dr. Samuel Gache, of Buenos Ayres, República Argentina; "On the Methods Employed for the Prevention of Disease and Preservation of the Lives of the Inhabitants of the District of Columbia," by Dr. Charles M. Hammett, of the city of Washington, health officer of the District of Columbia; "La Embriaguez: Sus Causas, sus Efectos, Urgente Necesidad de Disminuirlos. ¿Cuáles Serían los Medios más Adecuados Para Obtenerlo?" by Dr. Salvador Garciadiego, of Guadalajara, Mexico; "The Study of Type in Relation to Suicide," by Dr. Roland G. rtin, of Philadelphia, Pa., ex-president of the American Climatological Association.

After a few closing remarks in English and Spanish by the president, to whom a vote of thanks was then tendered, the section adjourned at 11 A. M. to meet in general session with the Congress.

## PAPERS READ BEFORE THE SECTION.

ON THE PROPER STATUS OF THE MEDICAL PROFESSION IN THE  
GOVERNMENT OF NATIONS.

By CORNELIUS G. COMEGYS, M. D., of Cincinnati, Ohio,

*President of the Academy of Medicine.*

Mr. PRESIDENT: In the presence of this august assembly of representative men of both continents of the Western Hemisphere, it seems to me an auspicious moment for the consideration of the relations which should exist between our profession and the executive departments of governments. Some are startled at the proposition that a physician should be made a minister of state, holding a position and exercising functions in regard to public affairs on a parity with the heads of other departments in the cabinet of a nation. In the history of governments the medical profession has not only been tolerated, but in those that stand on the highest plane of civilization it has been fostered by subventions of the state, and in order that the people could receive the full benefit of our beneficent art, liberal provision was made for the construction of edifices, libraries, laboratories, and museums for scientific culture, and free access given to hospitals for the observation and treatment of diseases and injuries. In this magnificent capital of the United States, the Government through the operations of the Surgeons-General of the Army, Navy, and Marine Hospital, has made liberal expenditures for the establishment of a national medical library and museum, the publication of an index catalogue and the army medical records of the civil war, and for researches at home and abroad on the origin and nature of epidemic diseases likely to be brought to our shores by immigrant and other ships, but beyond these sanitary provisions our central Government does not go. There is no office here for the collection of facts in demography and hygiene; no means provided for the exploitation of measures that could direct continuous scientific research in regard to endemic and epidemic diseases in every part of the nation. Nevertheless, through the influence of the American Medical Association, State boards of health have been organized in most of the States, but no central office exists in Washington, in which data can be brought into a uniform expression that will present the conditions in demography and hygiene that have been attained in English and Continental States in Europe. On this account an active movement is now in progress by the American Medical Association to obtain an act of Congress to establish a department and a secretary of public health.

In primitive history we find that Hygeia and Therapy formed so conservative a feature in the afflictions of people that wise men, instead of seeking laboriously in the known arts and sciences for an explanation of the success of medical treatment, attributed it to the beneficence of the heavens, and so precious were the discoveries of preventive and practical medicine that the documentary testimony was carefully preserved in the temples of religion; indeed in theocratic governments they became a part of the instruction of the priesthood. We can not read without admiration of the wisdom and forethought which made sanitary measures a part of the religious code of the people. The hygienic laws of Moses, which undoubtedly embodied fragments of his Egyptian training both as a priest and physician, and the moral code, the Ten Commandments, received from the hands of God, have been kept together by the Jews in the structure of their holy books, and sacredly practiced for thousands of years, which clearly accounts for their

existence physically and mentally as one of the strongest races among the multitudes of the earth. A glance at the past shows that the course and development of hygiene on one hand and the progress of the sciences and growth of the mind on the other, have constituted great factors in the evolution of humanity; nevertheless, in modern times medicine has not held the rank and dignity in the executive department of governments that have been allotted to jurisprudence, diplomacy, arms, and finance, notwithstanding the maxim which has descended from the remotest ages, "The health of the people is the supreme law." An enlightened and liberal investigation of the medical office shows that it appertains to a most important function in a commonwealth. There are no evils in society that physicians have not a large ability to restrain; there are no foes of human happiness so widespread, miserable, and despairing as those which undermine public health. An English physician of great distinction said a score of years ago, in a public address, "I think it will be well for the State when the profession to which we belong is represented in the councils of the nation as weightily as can be assured by official places and conferred dignities." It is impossible to exaggerate the value to a State of the medical profession; it envelopes and penetrates not only the individual but the social and political fabric as well. It is productive and conservative in its ministrations. We are pledged to alleviate suffering and contend against death. We also are teachers of the laws of health and walk as sentinels about the encampment of the multitude. In war we go with armies to care for the fevered soldier and follow him through the thickest of the fire not to aid destruction in her work but to staunch the wounds she makes. It is not the bugle call nor the roar of battle that arouses our activity, but the cries of the wounded and dying, the appalling ruin of the field. In our civil practice, on every hand is infirmity, despair, death; hoping to strengthen or to avert, our days are occupied; in the effort to sustain the hopes, the agonies, the distress of society our burdens are often too heavy to be borne. These are not overdrawn statements; there are many in this audience who can verify them. It is certainly a remarkable spectacle, the constant effort of physicians to save the people from disease when success will limit to the smallest dimensions the practice of medicine. But this grows out of the nature of their studies, the tendency of which gives the highest motive for unselfish service to humanity. The physician is bound to render service to the poor and rich alike. The amount of gratuitous service, especially in great cities, constitutes one-third of their practice. The most distinguished and experienced of the profession form the staffs of all of our hospitals and without salary. If there were cruelty to prisoners on either side in our civil war, it was not perpetrated by the surgeons of the opposing armies; and when the strife ceased they were the first to extend the fraternal hand across the field of conflict. Prompted by the most noble instincts, physicians in their efforts to enlighten the lowest races have distinguished themselves in geographical discovery. Dr. Mungo Park whilst traveling among the barbarous Africans discovered the great Niger; Dr. David Livingston in our times, actuated by the same motives, found the Congo and the vast lakes which are the sources of the Nile; Drs. Kane and Hayes, of Philadelphia, in their search for the lost voyager, Franklin, penetrated into the Arctic Ocean farther than any former travelers. A multitude of physicians have gone with religious missionaries in their efforts to shed the light of our civilization on barbarous and semicivilized peoples in every part of the globe. Success in missionary efforts is only made possible by the culture and works of beneficence displayed by medical men and women. Until physicians entered China there existed no scientific knowledge of anatomy and physiology. Surgical science was not known sufficiently to lead the doctors there to tie a bleeding artery, and there was no relief for women in the cruel adversities of parturition, nor was there any knowledge or practice of

hygiene, nor any measures for staying infectious diseases. In 1834 Dr. Peter Parker, under the patronage of the Presbyterian Church in this country, established the first hospital in the city of Canton. Since then five other ports have been opened to missionary work, and there now exist 60 hospitals and dispensaries, and several hundred physicians are constantly practicing among the people. In Parker's hospital there have been performed 1,600 operations for stone and with marvelous success; and during the year 1892 there were saved over 100 women in childbed, who would have perished in the hands of native practitioners. In India the British Government has established 1,600 hospitals and dispensaries, and besides these Christian missionaries have created a large number. Medical schools have also been opened under the English patronage, and thousands of natives have been instructed systematically in medicine, and incalculable relief has been furnished to the people in sickness. The superiority of the equipment and training of the English army led to the conquest of India, but the great skill and success in the practice of medicine has won the confidence of the people and helped them to become reconciled to their conquerors. Civilization can not be established permanently without the science and practice of medicine. A great race of men is slowly perishing within the Government of the United States, which might long since have been made productive, intelligent, and peaceable citizens if certain numbers of their youth had been separated from the wild, warlike life of the wigwam and trained in the common, technological, and professional schools of civilization. Instead of this they have been preyed upon and demoralized by the agents and the post traders of their reservations. It is reasonable to believe that medical capacity and its humane influences would have been a powerful factor in their regeneration if it had had more influence in the executive department of the Government. It is not too late to save the remnant from the impending destruction. The medical profession holds itself ready, as it always has, not only to diminish the destruction by disease, but ultimately to destroy the contagions that cause it. It is well understood that infectious diseases and toxic elements are disseminated as food; that diseases in the family of a dairyman, or among his cattle, may be as widely diffused as his distribution of milk. The pollution of rivers, streams, and wells in towns, villages, and farmers' homes subject families to tedious and fatal diseases which a wise sanitation could avert. It is so absolutely demonstrated that by a rigid application of hygienic laws the ravages of a pestilence may be arrested, that medical scientists speak of such destruction as a self-imposed cause of dying in the prime of life. The progress of medicine in saving life in times of great distress is shown in the practice of midwifery and surgery. In a maternity hospital in Philadelphia not a single death has occurred in 1,500 successive cases, and in the maternity hospital in Paris over 2,000 successive deliveries have occurred without a fatal case. The deaths in capital surgery have become so rare that surgeons undertake with great confidence the most formidable operations and expect recovery without a drop of pus. Inflammations and fevers are now known to depend upon the presence of pathogenic germs; in the former the pernicious action is prevented by asepsis; in the latter by a treatment that will eliminate the toxic elements in the blood as rapidly as they are formed. On the other hand, one-half of the children in our crowded cities die under 5 years of age. This fearful mortality can be reduced one-half under the operation of sanitary laws directed by physicians. In the census reports of the United States for 1890, more than 500,000 deaths are enumerated in the different States. It is the medical belief that preventive medicine would have saved one-third of the lives.

Another subject, and one of the highest importance to the working classes, who are, so to speak, wards of the medical profession, has recently been developed by Sir James Crichton Browne, M. D., of England, which shows how much responsibility rests upon us to carefully investigate the wear and tear of the neuro-

muscular system by overwork. He proves incontestably that, owing to the strain in what is called "piece work," a workman who at 30 years of age can make 45 shillings a week and should be able to continue it for thirty years, finds that, strive as he may, he can not at 45 earn over 38 shillings, and at 55 he can earn no more than 28 shillings. A knife maker, who, by striking 28,000 blows a day with his hammer, can earn a good living, can not continue to earn half that much at fifty years of age. In all of these cases the failure is shown to be in the neuro-muscular systems of the arm and shoulder. Is not this a high example of cruelty to animals? Must not the medical profession enter its protest? Does not this concern statesmanship? But Sir James has carried his statistical investigations into the study of the limitations of life in the upper classes. For example, he says that while there is a marked decline of 17.6 per thousand in the death rate in all ages under 35, owing to the improved sanitation in the whole country, there is only a decline of 2.7 per thousand above 55 years; while between 65 and 75 the death rate is increasing. He adds that it is not very satisfactory to learn that while in babies and young people there is an enormous increase in longevity, the increased loss is alarming among those eminent in experience and judgment. He next shows that this decay in the mature element of society is found in a few groups of degenerative affections, thus: In cancer, in a period of thirty years, the increase is 134 per cent; in nervous diseases, 32 per cent; in kidney diseases, 164 per cent; in heart diseases, 143 per cent. He believes that this increased mortality is due to the increasing luxuriousness in our advancing civilization. He also refers to the alarming increase of insanity. In the United States we have no registrar-general, so it is impossible to make such demographic investigations. Are not the above researches a function of statesmanship? The importance of higher medical education is conceded now by all true physicians, and our best schools have undertaken to accomplish it. The great hindrance to its achievement lies in the lack of a central office in Washington of sufficient rank to exert an influence for a concerted action to that end, among the one hundred schools in the States. The American Medical Association has by its efforts secured annual meetings of the college authorities to consider the subject, and much progress has been made. Entrance examinations are now the rule, and the period of study is being lengthened to four years in several schools. All true physicians desire that all graduates shall command the respect and confidence of the people as thoroughly trained scientific men; in fact, ranking among the best educated men, in all respects, in a community.

There is another value that will be an outcome of higher practical education. It will be possible for physicians to undertake the instruction of the agricultural classes in the elements, at least, of chemical, physical, and biological science, by organizing in country towns courses of instruction in the winter season, wherein, by means of lectures and experiments, illustration and simple text-books, primers in science, they will be able to impart extensive instruction to this great but sadly neglected portion of our population and by which their practical power as producers will become greatly augmented and their social happiness increased. The freshest and strongest minds are found among farmers. This is an elevated and legitimate work for doctors. The organism called "medicine," like every other product of man's constructive genius, is striving to attain perfection, and to accomplish this it must be sustained in all its scientific undertakings by the coöperation of national and State legislation and by the people. Medicine has never been cultivated in the highest degree where it has had imperfect recognition as an element of the State. In the British and continental governments in Europe it has always had the watchful care of the state, and eminent practitioners are frequently receiving titles of distinction both from universities and chiefs of states. The degrees of LL. D. and D. C. L. are given to eminent medical men not only

here but by monarchs of Europe. These titles indicate their competency in statesmanship. Our methods of research are the same as those employed by lawyers, engineers, machinists, and by learned men in the whole range of the natural sciences; and the opinions of well-trained physicians are as certain as those given by judges, statesmen, architects, engineers, divines, bankers, and merchants.

Let me speak briefly on the increased light which physiology and pathology have shed on the relations of the brain and the mind. For a long time the brain has been known as the center of sensation and motion, but only within a few years have they been located in the special areas of that organ; but now we know the very seat, not only of sensation and motion and of their coördination for the execution of instinctive and purposive movements, but we can put our fingers on the exact region where sensations are shaped into concepts, where ideas are symbolized in language, where memory has its seat, and the imagination displays its marvelous powers. All the apparatus of respiration, of digestion, of circulation, of the vast neuro-muscular system, is merely to sustain a certain definite area in the brain which we can cover with our two hands; it is the realm of consciousness—the plane where spirit and matter greet each other, so that a man can say, “I know that I know;” “I feel that I feel;” “I think that I think;” it is where the consciousness is in equipoise with the immensity of the cosmos. Gravitation is instantaneous; consciousness just as rapidly reaches from the center to the circumference of the universe. Who has the right to supervise this dread region but the physician? Closer than the minister of religion, or the ties of blood, he is the guardian of its illimitable faculties. Through physiological and pathological research, psychology has been lifted above the subtle reasoning of the schoolmen into the light of a new day, and it is now comprehended as never before. Metaphysics is no longer a jugglery with words, but is a function of consciousness existing only in the healthy brain. It is the purest and highest expression of reason and a free will, and can not be displayed but by the healthy brain. It is a psychological systemization of terms under the regulative faculty, the will, whereby the intuitional phenomena of thought and the phenomena derived through the senses from external objects—the ideal and the real, the subject and the object—are brought into accord, and the mind is freed from baleful illusions, hallucinations, and delusions. The imperfect state of consciousness in unsound sleep wherein ideas flow, regulated only by their automatic association, represents the abeyance of the metaphysical function. We are led everywhere by the most grotesque, absurd, and fearful ideation without self-control. There is no metaphysics in dreams, nor is there any responsibility for the actions or thoughts of a person in dreams, because his consciousness is not under the regulation of will. He may know right from wrong in dreams, but he is irresponsible.

Physicians, because of their knowledge of the brain and the mind, possess abilities for broad and useful services in the social and political state, and no man in the Cabinet would serve better as a counselor to a ruler than an expert physician.

I have shown that the regulative faculty of the mind—the will—is not a transcendental entity to be considered apart from physical existence, but, so to speak, is the correlative of the total organic power of the brain, and is therefore amenable to sound hygienic laws, without the operation of which this magnificent endowment of man can not be displayed. Let the fine physical organization of the brain suffer deterioration from any cause and the man no longer controls his ideas, but on the contrary he is led by them and too often driven. We warn men, but they do not heed us. They mock our solicitude and boast of their capacious powers, but sooner or later the wear and tear shows itself—the pilot is losing his keen eye and firm grasp of the helm. The stupendous ventures in stocks and produce in the great centers of commerce are frequently manifestations of intellectual perversion, superinduced by the constant excitement attending these operations,

Every faculty of the dealer's mind, intellectual and emotional, is urged without restraint beyond normal capacity; his reason is in abeyance; his actions are impulsive and dangerous to his environment. To grasp, to conquer, to accumulate, to control, to hate, to lust, any or all of the terrible elements of evil, may arise and govern the life of a man. His reason is subrogated to his passions, which like ferocious beasts are ready to leap upon and destroy his existence. The morbid drama now being enacted in our financial world is simply the outcome of the delirious speculation that has raged for years past. Luxury and vice have clung together and formed the deadly moral dynamite whose destructive force is seen in every direction. These catastrophies have been predicted by medical psychologists for years past. History furnishes fearful examples of the ruin of states and empires because of the licentiousness, tyranny, and an inappeasable thirst for conquest of men whose early characters exhibited self-denial, justice, and peace.

I have not the time for an elaboration of these important questions, which include the physical, moral, and intellectual culture of the rising generation of a State. It was a subject that deeply concerned the eminent statesman and physician of our revolutionary era, Dr. Benjamin Rush. I will briefly add that there are no fortuitous conditions that concur for the best political circumstances of the State; the whole is purposive intelligence existing in the individual and combined for the exigencies of society. Wherever the highest development of physical health exists there will be found the surest basis of the best mental faculties. These are not mere abstract themes of philosophy, but the most practical questions of the day, interesting not only to the people at large, but especially to those who control the destinies of nations.

The question may arise whether the proposed department of public health would subserve the interests of any particular school. I reply no; that amid all the apparent disparity in medical practice there is one true severe unity, and to attain this all true physicians are continually striving. With the advance in the way of higher education the differences in modes of treatment will gradually disappear. There is no disputation in medical science in regard to anatomy, physiology, pathology, chemistry, physics, or preventive medicine. The general modes of practice will become gradually unified.

I now insert an extract of the bill which was introduced in both Houses of the last Congress of the United States, and which still remains on the files of the committees to which it was referred, in order to show its intent.

A BILL to establish a department of public health.

*Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled,* That there shall be established a department of public health. There shall be appointed from civil life by the President, by and with the advice and consent of the Senate, a secretary of public health, who shall be intrusted with the management of the department herein established. He shall be paid an annual salary of ———. He shall, with the approval of the President, provide suitable offices for the department, and shall employ such assistants and clerks as may be necessary.

SEC. 2. That it shall be the duty of the Department of State to obtain from consular officers at foreign ports and places all available information in regard to sanitary conditions of such ports and places, and transmit the same to the department of public health; and the secretary of public health shall also obtain, through all sources accessible, including State and municipal authorities throughout the United States, weekly reports of the sanitary condition of ports and places within the United States, and shall prepare, publish, and transmit to the medical officers of the Marine-Hospital Service, to collectors of customs, and to State and municipal health officers and authorities weekly abstracts of the consular sanitary reports and other pertinent information received by said department. The said department also shall, as far as it may be able, by means of the voluntary coöperation of State and municipal authorities, of various general and special hospitals and sanitariums, of public associations, and of private persons, procure and tabulate statistics

relating to marriages, births, deaths, the existence of epidemic, endemic, and other diseases, especially those of a degenerative character, such as malignant growths and affections of the circulatory, respiratory, secretory, and reproductive organs, and data concerning the fruit of incongruous marriage and transmissibility of insane, alcoholic, syphilitic, nervous, and malignant types of constitution. He shall also procure information relating to climatic and other conditions affecting public health, especially in reference to the most favorable regions in the United States for the cure or relief of the chronic diseases of the several organs of the body, especially of consumption. He shall also obtain information in a sanitary point of view of the health and comfort of the laboring classes. He shall seek through the State boards of health information in regard to the healthiness and comfort of public schoolhouses. He shall, so far as he can, further collective investigations in regard to the common diseases of an inflammatory and febrile character that prevail among the people. He shall coöperate with State boards of health, the Signal Service, the medical departments of the Army, Navy, and Marine-Hospital Service, and unify and utilize their work so as to make the department of public health a repository of the most important sanitary facts that concern the public comfort. Besides the reports of the state of public health, which he shall make from time to time, the secretary of public health shall make an annual report to Congress, with such recommendations as he may deem important to the public interests; and said report, if ordered printed by Congress, shall be done under the direction of the department.

The question I submit is this: Have we qualifications, through the operations of our profession, to contribute to the progress of Governments, increasing happiness, intelligence, and public virtue? If we affirm that we have, then shall we not claim the rank and dignity in the State that will give us the highest opportunity for their exercise?

## OJEADA RETROSPECTIVA SOBRE LA ORGANIZACIÓN DE LA SANIDAD EN LOS EJÉRCITOS ESPAÑOLES. PRIMEROS ALBORES DE LA MEDICINA MILITAR EN AMÉRICA.<sup>1</sup>

Por el Doctor FELIX ESTRADA CATOGRA,

*Médico del 10º Batallón Artillería del Ejército de la Isla de Cuba.*

No es posible separar la historia de la medicina militar de la de los ejércitos en campaña, por lo que hace á nuestra patria, pues doquiera acudieron las tropas españolas, fueron acompañadas de físicos y cirujanos que en medio de las batallas, en los rigores del combate, restañaron la sangre de los heridos, curaron las enfermedades de los combatientes, sufriendo las penalidades del soldado, participando de todas las calamidades de la guerra. Y no solo ha pasado así desde el invento de la pólvora, desde la aplicación de la artillería, sino desde los primitivos tiempos de nuestra historia, como es fácil comprobar por la lectura de los códigos más antiguos.

No es extraño que así sucediese, si se tiene en cuenta que la medicina vulneraria ha sido una de las primeras conquistas hechas á la naturaleza en las primeras edades del mundo, como dice un galano escritor que tuvimos por maestro.<sup>2</sup> “Allí donde por primera vez luchó el hombre de un modo material”—dice un historiador de nuestros días—“por defender su derecho, ó por dar amplitud á sus deseos y aspiraciones, y hasta satisfacción á sus vicios y malos pensamientos, allí empezó la medicina militar. Primero la lucha, después el modo de remediar sus estragos, esto es lógico; en todos los países ha tenido que suceder así y por consiguiente en España.”<sup>3</sup>

<sup>1</sup> Este trabajo constituye el primer capítulo de una memoria inédita sobre el origen, organización y servicios de la sanidad militar en Cuba que pensamos publicar.

<sup>2</sup> Vicisitudes y progresos de la medicina como ciencia y arte en relación con los demás conocimientos. Discurso del catedrático de patología de Santiago, D. Ramón Otero.

<sup>3</sup> Historia de la Medicina Militar Española, por D. Antonio Población.

Recorramos la Iliada y la Odisea, que podemos considerar como primitivos anales de las ciencias médicas, y allí veremos al hijo de Apolo, al gran Esculapio, descendiendo á la tierra para enseñar á los mortales el arte de curar y evitar la fria segur de las inflexibles Parcas. También Homero canta en inmortales versos el valor de Podalíro y Chiron, y de otros príncipes que en los campos de batalla alcanzan gran renombre, no sólo por sus heróicos combates, sino también por la habilidad que muestran al restañar la sangre de los heridos.

Probado está por las investigaciones de literatos y médicos, que los ejércitos griegos y romanos contaban con médicos y cirujanos que los acompañaban en las guerras. Simpson,<sup>1</sup> Kühn<sup>2</sup> y Aubertin<sup>3</sup> han demostrado la existencia de médicos militares en las legiones egipcias, griegas y romanas, y en todos los ejércitos de la antigüedad.

Nuestra patria, teatro de grandes acontecimientos militares desde los primeros conquistadores, centro de luchas y discordias intestinas al constituirse la monarquía goda, en combate con los árabes durante algunos cientos de años para reconquistar el territorio, fué sin duda una de las naciones en que más predominó el espíritu guerrero en que más necesarios se hicieron los servicios humanitarios para asistir á los combatientes heridos en las frecuentes luchas; así no es extraño que los servicios medico-castrenses tengan en nosotros un origen más antiguo que en las demás naciones de Europa, y así también que durante muchos años España marchase á la cabeza en cuanto se refiere á la organización sanitaria de los ejércitos.

En casi toda la Edad Media, así en España como en otros países, la medicina era estudiada y practicada muy especialmente por los judíos, tan numerosos en las naciones cristianas y muy particularmente en la nuestra, cuanto que las leyes que contra ellos promulgaron varias veces los reyes godos posteriores á Recaredo, eran inspiradas por el miedo que hubo de que llegaren á formar de España un estado judaico, atribuyéndoles también gran participación en la conquista árabe. El Fuero Juzgo contiene leyes expresamente aplicables y referentes á los médicos judíos, por cierto bien crueles y absurdas, pues entre estos hubo verdaderos sabios que hicieron progresar la medicina, como el famoso Yzdrag, médico del rey D. Alonso VII de Castilla y otros muchos que cita Hernández Morejón, como hábiles cirujanos que contribuyeron al adelanto de la medicina patria.

El establecimiento de hospitales en España es también de remotos tiempos, y aunque faltan datos anteriores al siglo doce, no sería difícil encontrar noticias aisladas aquí y allá, no tanto en las crónicas (que estas eran demasiado secas y concisas en los principios de la Edad Media) pero sí en los archivos monacales y otros de villas, ciudades é iglesias del reino, en que se habla de fundaciones de hospitales por nuestros reyes, en particular para leprosos, desde los primeros tiempos de la monarquía asturiana; pudiendo decir otro tanto de los demás estados en que se hallaba dividida la península.

Consta sí que en el siglo doce existían hospitales para curar los heridos de la guerra, siendo fundado uno en Toledo por D. Pedro Fernández de Fuentecalada, maestro de la orden de Santiago. En el castillo de Guadalherza lo estableció la orden de Calatrava, y otros varios citan los historiadores en distintos pueblos de la península, demostrándose que esta institución sanitaria para los ejércitos es más antigua entre nosotros que en otras naciones de Europa. Quizás la influencia que la dominación romana ejerció en España, fuese la causa de existir hospitales para la tropa en nuestro suelo desde muy antiguo, pues sabemos por Higinio el

<sup>1</sup> Was the Roman army provided with any medical officers? By J. Y. Simpson, president of the Royal College of Physicians of Edinburgh, professor of midwifery in the University, etc., 1851.

<sup>2</sup> De medicina militaris apud veteres Græcos Romanesque conditione. D. Carolus Kühn, etc., 1824 á 1827. Dissertations.

<sup>3</sup> Del servicio médico en los ejércitos de la antigüedad, por Ch. Aubertin, profesor de letras de la Universidad de Dijon, publicado en la Revue des médecins des armées.

Agrimensor, que los romanos en sus campos de guerra establecían el valetudinarium ó enfermería para sus soldados.

Las órdenes militares tuvieron también gran influencia en la creación de los hospitales, así como instituciones derivadas de ellas para la asistencia de los enfermos y peregrinos, no dejando de tener una gran participación en estas fundaciones las expediciones de los caballeros castellanos, aragoneses y navarros al Egipto y Palestina formando parte de las cruzadas en la conquista de Jerusalem.

Pero no vamos á seguir en este orden de ideas y volvamos á la fundación de verdaderos establecimientos dedicados á la hospitalidad de nuestras tropas. Los primeros hospitales de campaña organizados en todos sus servicios fueron los establecidos en España por Isabel la Católica. Hernan Pérez del Pulgar, al escribir sobre la conquista de Granada, dice: "É para curar los feridos é los dolientes, la reina enviaba siempre á los reales seis tiendas grandes, é las camas é ropa necesaria, é homes que les sirviesen, é mandaba que no llevaren precio alguno, porque ella lo mandaba pagar; é estas tiendas con todo este aparejo se llamaba en los reales el hospital de la reina."<sup>1</sup>

Pedro Martir de Angleria, que formaba en el ejército español el año 1489, escribió desde el sitio de Baza al cardenal arzobispo de Milán sobre este hospital, elocuentes frases que demuestran deben su origen los hospitales de campaña á la munificencia de la egregia Isabel, á quien tanta gloria debe España y la causa de la civilización.<sup>2</sup>

Pero si existían hospitales en nuestra patria y si la historia nos ilustra respecto á los que para la conquista de Granada estableció la reina católica que podemos considerar como verdaderas ambulancias de campaña, si la legislación médico-militar la encontramos en las leyes de partida del sabio D. Alonso, si es fácil demostrar que á los ejércitos acompañaban médicos y cirujanos, no es tan fácil comprobar la organización dada á estos para el cumplimiento de sus servicios. No podemos dejar de estar conformes con el historiador médico-militar Sr. Población que dice sobre este particular:

Pero es indisputable que los médicos, cirujanos, farmaceúticos, practicantes y enfermeros socorrieron con organización; que no podemos determinar los desastres propios de la guerra; que hubo dotación de efectos quirúrgicos y de medicamentos y que el personal fué recompensado más ó menos ámpliamente por el dinero particular de la reina Isabel.

Esta falta de datos que encontramos en el servicio de la sanidad militar del período de la historia patria hasta los reyes católicos, corresponde á la vez á la falta de una organización para el ejército, que hasta esta fecha no puede considerarse como un verdadero organismo para la defensa del territorio según aquellos monarcas establecieron después en sus pragmáticas. En 1505 vemos ya aparecer un cirujano en cada una de las compañías llamadas guardas de Castilla que sustituyeron á las hermandades de Castilla organizadas por D. Alfonso el Sabio.

Al terminarse el glorioso reinado de los reyes católicos, el ejército estaba necesitado de grandes reformas, que acometió el ilustre cardinal Ximenez de Cisneros, á quien se debe mirar como uno de los más sabios generales, pues su espíritu militar se hizo patente en más de una ocasión.<sup>3</sup> Dicho gobernante, al hacerse cargo de la Regencia en enero de 1516 trató, de formar un ejército respetable, oyendo la opinión autorizada de los militares más ilustres y conocedores de la guerra, entre

<sup>1</sup> Hernández Morejón: Historia de la medicina, f. 1, pág. 256.

<sup>2</sup> Clemencín: Elogio de la Reina Católica, Da. Isabel 1<sup>a</sup> de Castilla, pág. 176.

<sup>3</sup> Conocida es la anécdota histórica de haber enviado los grandes una diputación para preguntar al Cardinal Cisneros en virtud de que poderes gobernaba, y la contestación que dió á esta, llevándolos hacia el balcón de palacio y mostrándoles un cuerpo de tropas de artillería que estaban maniobrando con cañones, les dijo: "Esos son mis poderes," ante cuyo argumento digno de un gran general, los nobles comprendieron que bajo aquellos hábitos se ocultaba un alma enérgica, un corazón de guerrero. Podrá no ser cierta esta anécdota desmentida hoy por autoridades competentes, como la de la capa de D. Enrique el Doliente y otras que han corrido como válidas en nuestras historias, pero no decae por ello el mérito que, como organizador del ejército de España, tuvo Cisneros.

ellos el Coronel Rengifo que ya había presentado una memoria al Rey Fernando y cuyo trabajo aprobó Cisneros, dictando órdenes para su ejecución.

Dicho trabajo, que teniendo en cuenta su época es notable, comprende ordenanzas militares, sistema de alistamiento, vestuario, etc., se dictó á los pueblos y vecindades en 27 de mayo de 1516, formándose según las instrucciones<sup>1</sup> un cuerpo especial de 400 hombres llamados pardos, especie de guardia real, independiente de los lansquenets venidos de Alemania con D. Felipe, reformándose las compañías y tercios así como los mandos,<sup>2</sup> no echando en olvido en esta organización los servicios tan necesarios de los médicos, cirujanos y farmacéuticos,<sup>3</sup> así que al formarse los primeros tercios que fueron los de Lombardía, Nápoles y Sicilia figuran en la plana mayor estos destinos en el año 1534.<sup>4</sup>

Pasa para el cuerpo de sanidad militar el reinado de Carlos I sin modificaciones en el servicio que prestaba en las tropas, pero figurando médicos distinguidos en el ejército y en las campañas del ilustre emperador. Cuando Felipe II recogió la rica herencia de su padre, trató de corregir defectos que había en sus tropas, empezando por reformar el ejército de Italia y en las instrucciones que dictó en Toledo á 24 de diciembre de 1560,<sup>5</sup> figura en presupuesto un médico con 15 escudos y un cirujano con 12, afectando al servicio de la sanidad militar algunas de estas instrucciones, pues se disponía fueran dados de baja todos los inútiles,<sup>6</sup> sufriendo modificaciones el traje militar con arreglo á la higiene de aquellos tiempos.<sup>7</sup>

No estaba tampoco desatendido el servicio de hospitales militares de campaña, pues en el presupuesto, como diríamos hoy, formado en 6 de septiembre de 1591,<sup>8</sup> aparece la partida siguiente :

Para el gasto del hospital se descuenta á cada soldado un real cada mes, y á los

<sup>1</sup> Estos documentos, tan notables por la idea que dan del espíritu de la época, existen en el archivo general de Finanzas. (Estado, Secretarías provinciales, legajo No. 217), y los copió íntegros el Conde de Clonard en su Historia Orgánica del Ejército.

<sup>2</sup> En tiempo de los reyes católicos la unidad fué en un principio la compañía, después la columna ó coronelía distribuida en 20 compañías. Luego vinieron los tercios, compuestos cada uno de tres coronelías y cada una de estas con 12 compañías. Cada tercio lo mandaba un maestre de campo. (Clonard, f. 3, pag. 156.) Sin embargo, el nombre de tercios es tan antiguo en Castilla, que ya en mil setenta y tantos, en el reinado de D. Alonso VI, se dice que Dia Sauz y Fernán García mandaban en la conquista de Madrid los tercios de Segovia.

<sup>3</sup> La existencia de los farmacéuticos en los ejércitos data en España del tiempo de los árabes. En Francia también, bajo el reinado de Enrique II, tenían farmacéuticos militares los hospitales de Metz y Thionville; Sully, ministro de Enrique IV, nombró un farmacéutico militar para el hospital de Amiens, siendo Richelieu el que aumentó el número de farmacéuticos en los hospitales militares. (Ver Mallaina: Historia de la Farmacia.)

<sup>4</sup> La plana mayor de cada tercio comprendía: 1 maestro de campo con 40 escudos mensuales; 1 sargento mayor, 20; 1 furriel mayor, 20; 1 municionero, 10; 1 tambor general, 10; 1 capitán barrachel de compañía con 12; 1 teniente de idem, 6; 1 médico doctor, 12; 1 cirujano, 10; 1 boticario, 10; 1 capellan, 12; 8 alabarderos de la guardia de honor del maestre de campo á 4 escudos, 32; total, 194 escudos.

<sup>5</sup> Relación de lo que montará el sueldo de un mes de tres mil infantes españoles con diez capitanes y sus oficiales y ventajas. (Clonard, f. 3, pag. 428.)

<sup>6</sup> Véase un trabajo del Sr. Montejo Robledo sobre el servicio de declaración de inútiles publicado en la Gaceta de sanidad militar.

<sup>7</sup> Sabido es que el uso de verdaderos uniformes data del pasado siglo y después del advenimiento de la casa de Borbón. En Francia tampoco son más antiguos que Luis XIV. Anteriormente usaban libreas uniformes solo algunos pequeñísimos cuerpos más palatinos que guerreros, inmediatos á las personas reales como la guardia amarilla, la tudesca, etc. Nuestros soldados de Italia y Flandes vestíanse sí de colores vivos, con plumajes, cadenas y joyeles, pero á capricho de cada uno, haciendo expresa mención las numerosas leyes suntuarias de no quedar sometidos á ellos los soldados á quienes se dejaba en completa libertad de vestirse y adornarse á su antojo, libertad de que usaban y aún abusaban por la profusión de encajes, colores y zarandajas que se echaban sobre sus personas, en cuyo fausto se les distinguía á la legua de la población civil. Véase en apoyo de esto las comedias y novelas de la época.

<sup>8</sup> Relación de lo que montará el sueldo y gasto de cada mes de un ejército, en que haya dos mil y cien caballos y quince mil infantes, llevando doce piezas de artillería con los pertrechos y municiones necesarios, que todo suma ciento treinta y siete mil y cuarenta y cuatro escudos de á diez reales castellanos cada uno. (Clonard, *op. cit.*)

oficiales á más, y hereda algo de los que en él se mueren, y por lo que se ha de gastar agora de presente de golpe y se irá gastando adelante de más de lo que se contase, se ponen mil escudos al mes y aún se entiende que es poco.

Este dato arroja mucha luz sobre nuestra organización sanitario-castrense de aquellos tiempos.

La historia del cuerpo de sanidad militar marcha unida á la del cuerpo de sanidad de la armada en estos tiempos primitivos de organización. Como auxiliares y al servicio de los reyes y príncipes, vemos indistintamente á los médicos y cirujanos figurando en el ejército y en la marina, siendo fieles compañeros y amigos de los monarcas, como Diego del Villar lo fué de D. Alonso VIII, á quien curó de sus heridas en la desgraciada batalla de Alarcos, como Dionisio Daza Chacón, Luis Labera de Avila, Antonio de Guevara y Cristóbal Pérez de Herrera, que tan brillantes servicios prestaron en las campañas de mar y tierra de su época, y, por último, como el ilustre Pedro Virgilio, que siendo cirujano del rey Fernando VI fundó el colegio de San Fernando de Cádiz, origen de la restauración de los estudios quirúrgicos en España, oyendo del monarca aquella memorable respuesta á su petición: "Reparador de la salud de España, á tu voz van á abrirse mis tesoros, y esa obra fundada por tus manos, dirigida por tí, ha de guardar tus leyes y estatutos." Al colegio de Cádiz fundado en 1748 para el servicio de la armada, siguió el colegio de Barcelona en 1764 para el ejército, de cuyos dos colegios, según algunos historiadores, fué director el mismo Pedro Virgilio; pudiendo estos datos y otros más que sería fácil recojer, corroborar la íntima unión que existía en su principio en los cuerpos de sanidad militar y de la armada, unión justificada por la semejanza de sus servicios.<sup>1</sup>

No debemos pasar tampoco por alto sin citar como predecesores de esta organización en los servicios sanitarios, los que prestaron las órdenes militares de Santiago y Calatrava, así como la hermandad de San Juan de Dios que figura asistiendo á los heridos y enfermos de las tropas, no solo en las guerras contra los moriscos de Granada, sino en la expedición á Tunez, en la conquista de Portugal, en la de las Islas Terceras por el almirante Bazan, y en cuantas campañas de mar y tierra emprendieron nuestros compatriotas en los siglos diez y seis, diez y siete y diez y ocho.<sup>2</sup>

Indudablemente que estos servicios prestados por las instituciones religiosas, que los hospitales fundados en Toledo, Cuenca, Granada y otras ciudades, no revelan una organización perfecta del cuerpo de sanidad militar, pero manifiestan lo que fueron sus primitivos tiempos, confirmando lo que decimos al empezar este trabajo, que la historia del ejército es la de nuestro cuerpo.

No parecerá pues extraño que al intentar bosquejar el origen, organización, y servicios en la Isla de Cuba del Instituto de Sanidad Militar á que nos honramos en pertenecer, tratemos de remontarnos á una época tan lejana cual es el descubrimiento de América. Aunque la flota que condujo al ilustre navegante en su primer viaje no tenía una organización militar verdadera, es indudable que

<sup>1</sup> El colegio de San Carlos de Madrid fundóse en 1787 por el cirujano militar D. Antonio Gimbernát en vista de los brillantes resultados que en el ejército y en la marina producían los de Cádiz y Barcelona.

<sup>2</sup> Los hermanos Obregones, instituto fundado por Bernardino de Obregón, caballero del hábito de Santiago, establecieron varios hospitales en España, extendiendo sus servicios por el Oriente y las Indias, dejando escritos entre otras una Instrucción de enfermos y modo de aplicar los remedios, de gran utilidad para la práctica de los servicios hospitalarios. La hermandad de San Juan de Dios tuvo su origen en 1543, fundando su primer hospital en Granada de donde se distribuyeron por varios pueblos de la Península, y la buena acogida que le dispensaron los grandes señores, les hizo fundar otras casas en América. Tanto los Obregones como los Juaninos, llegaron á alcanzar gran preponderancia, pues no solo servían en los hospitales, sino que llevados de su celo religioso y amor á la humanidad, acompañaban á nuestras tropas en sus campañas. Análoga institución á la de San Juan de Dios fundó en México, en 1591, Bernardino Alvarez, con el nombre de Hermanos de San Hipólito por radicar en su hospital de este nombre. Se aumentó bastante esta congregación fundando varias casas hospitales en Nueva-España.

aquellas caravelas que señalaron la ruta de los más grandiosos descubrimientos, no iban huérfanas de auxilios médicos; entre aquellos hombres intrépidos y avezados en las luchas, llenos de fé en las palabras del insigne descubridor, no podían faltar algunos maestros en la ciencia de curar. Tanto más debe creerse que así sucediere, cuanto en aquellos tiempos, debido á nuestras guerras con los moriscos, no faltaban maestros cirujanos y médicos en la Península; la medicina era seguida por muchos que sin estudios teóricos obtenían su práctica en los campos de batalla, en las epidemias de los encampamentos, en los sitios de las villas y ciudades.

Al genio previsor de Colón que dispuso sus bajeles, pertrechándolos para tan largo viaje de exploración,<sup>1</sup> no pudo pasar desapercibida la falta de cirujanos que curasen los heridos que era de pensar había de tener en sus conquistas, y que asistiesen en las enfermedades de la mar que tan frecuentes eran en aquellas fechas en las tripulaciones, y de que tan terrible memoria quedó después en otras expediciones, como en la de Vasco de Gama, la de Magallanes, y otras varias.

Tanto más de presumir es que llevasen en sus caravelas medios de atender á sus enfermos, cuando Colón fué aconsejado para emprender su viaje por los padres de la Rábida, á cuyo talento no podían escaparse las necesidades de una empresa tan arriesgada. No es posible fuese desprovista de recursos sanitarios una expedición tan estudiada, cuando la medicina había tomado ya parte en otras anteriores. Por la historia sabemos que en el siglo trece el cirujano Juan Pittard acompañó á San Luis á Tierra Santa; y si bien de la época de que hablamos no se sabe como se prestaba la asistencia facultativa en las naves, ni el origen, modo, y forma de los nombramientos, se sabe que no faltaban á los expedicionarios de mar y tierra estos servicios humanitarios.<sup>2</sup>

Tampoco podemos considerar á Colón menos previsor que á su competidor Américo Vespucio, que con Alonso de Ojeda y Juan de la Cosa, arribaron en 1499 á Venezuela, y que según Pacheco, "en esta expedición iban provisiones de todas especies, harina, legumbres, objetos de farmacia, artillería, de todo se había reunido en abundancia."

En efecto, corroborando nuestras suposiciones, se sabe que en la Santa María estaba, en 1492, el Maestre Alonso, físico<sup>3</sup> de Moguer, el que sin duda se alistó voluntariamente para aquella expedición, compuesta en su mayor parte de los valientes hijos del famoso puerto de salida. En la lista de tripulantes de la Santa María figura el Maestre Alonso después de los dos pilotos, Juan de la Cosa y Sancho Ruiz, lo que confirma su destino de médico de la embarcación, de la misma manera que en nuestros buques actuales forma el oficial de sanidad después de los oficiales de mar.

Que la primera expedición de Colón no iba huérfana de servicios médicos es tan seguro, cuanto que, entre los 38 hombres que al mando de Rodrigo de Arana dejó el descubridor en el fuerte de Navidad cuando volvió á España inmediatamente después del descubrimiento, había un Maestre Juan, cirujano, buena persona, dice Gonzalo Fernandez de Oviedo,<sup>4</sup> al que más adelante le llama hombre de bien, gentil cirujano.<sup>5</sup> Herrera también lo refiere en sus Décadas,<sup>6</sup> añadiendo que dejó además entre aquellos hombres un carpintero de rivera, un sastre, un tonelero, un calafate, y un artillero.

<sup>1</sup> Se sabe que llevaban víveres para un año.

<sup>2</sup> Los reyes y grandes señores fueron siempre acompañados de físicos, médicos, y cirujanos. Vemos en 1625 á Andrés Tamayo nombrado médico de la armada que llevó á D. Fadrique de Toledo á la recuperación del Brasil. Alejo Abreu acompañó á Hurtado de Mendoza en su expedición al Congo y Angola, y otras muchas citas podríamos hacer que creemos innecesarias.

<sup>3</sup> Ya en las siete partidas se llama físico al médico de la hueste.

<sup>4</sup> Historia General de las Indias, Libro II, Cap. VI.

<sup>5</sup> Libro II, Cap. XII.

<sup>6</sup> Década 1ª, Libro 1º.

Muchas veces omiten los historiadores tales pormenores, pero debe entenderse que en todas aquellas memorables expediciones de los conquistadores españoles llevaban médicos y cirujanos, máxime cuando no olvidaban ni los más insignificantes detalles en otros puntos de menor interés.

Por otra parte no es posible suponer que aquellos ilustres monarcas de Castilla, tan interesados por la salud de sus tropas que organizaron hospitales militares para la conquista de Granada, dejasen marchar sin asistencia facultativa una expedición á la que contribuyeron tan poderosamente para honra imperecedera de España, é inolvidable memoria de sus preclaros nombres; y efectivamente en la condición décima de las capitulaciones acordadas y firmadas el 17 de abril de 1492 entre Fernando é Isabel y Cristobal Colón,<sup>1</sup> aparece el acuerdo de que hubiese médicos, siendo el primero que obtuvo nombramiento real el Dr. Diego Alvarez Chanca en 1493, que era médico de la princesa primogénita de los Reyes Católicos.<sup>2</sup> No consta que este ilustre médico acompañare á Colón en su primer viaje, pero sí está probado que le siguió en su segundo viaje á América, escribiendo á su regreso una carta al cabildo de la catedral de Sevilla en la que describe las costumbres de los habitantes de la Isla Española ó Santo Domingo, que puede verse en las biografías de este médico, así como en la obra de Fernandez Navarrete, "Colección de viajes y descubrimientos de los Españoles."

Por Real Orden, 6 de Enero de 1501, dada en Sevilla, se previene al Almirante Colón nombrase los facultativos para su escuadra, así como en 1560, por Real Orden 20 de Febrero, se autorizó al Capitán-General del Océano D. Alvaro de Bazán, primer Marqués de Santa Cruz, para expedir los nombramientos de los profesores de los buques de guerra en representación de Su Magestad.

Como digimos anteriormente, estaban unidos los cuerpos de sanidad del ejército y la armada, prestando servicios de mar y tierra, ilustrados médicos y cirujanos que acompañaron las expediciones de Colón, Hernán Cortés,<sup>3</sup> Pizarro y demás intrépidos navegantes, honra de España y admiración de las generaciones posteriores. Por desgracia, la mayoría de los médicos y cirujanos que prestaron sus servicios en aquellas conquistas, han pasado sin dejar rastro en los anales de la historia y solo algunos cuyos escritos se estiman y conservan, como el citado de Alvarez Chanca, pasaron á la posteridad para honra de la medicina militar.<sup>4</sup>

Bién sentimos no poder seguir la historia médica de la primera expedición salida el Viernes, 3 de Agosto de 1492, del puerto de Palos, é indicar las enfermedades y asistencia que tuvieron aquel puñado de aventureros, valientes tripulantes de las frágiles caravelas. Consignarémos sin embargo que la salud de los navegantes debió ser excelente, á juzar por lo que refiere Colón en su diario, pues dice con fecha 27 de Noviembre: "Loado sea Dios Nuestro Señor, hasta hoy de mi gente no ha habido persona que le haya mal la cabeza, ni estado en cama con dolencia, saber un viejo de dolor de piedra, de que él estaba toda su vida apasionado y luego sanó al cabo de dos dias. Esto que digo es en todos tres navios. Así que placirá á Dios que vuestras altezas enviáran acá e venrán hombres doctos y verán despues la verdad de todo."

Poco sabemos más que esto para ilustrar la historia médico-militar de aquellos tiempos, y si hemos citado el hecho de acompañar á Colón en su primer viaje el

<sup>1</sup> Según hace constar el "Estado general de la Armada" existe este documento en el Archivo Real de Indias de Sevilla.

<sup>2</sup> Cartas autógrafas de D. Fernando y Da. Isabel á dicho médico.

<sup>3</sup> Este ilustre conquistador tenía el mayor cuidado con sus heridos como puede comprobarse leyendo á Solís (Conquista de Méjico). Como es sabido acompañaba á Cortés Fr. Bartolomé Olmedo que poseía la medicina, siendo tal la afición á curar entre la tropa que Solís, Herrera y Bernal Diaz del Castillo hablan de un soldado, Juan Cathalan, que hacía curas maravillosas en los heridos, citando también hasta una muger, Isabel Rodriguez, que obró curas admirables.

<sup>4</sup> Hernandez Morejón se estiende sobre el mérito de Alvarez Chanca, primer médico que estudió las costumbres y enfermedades de los Indios.

físico de Moguer Maestre Alonso así como el Maestre Juan, y en el segundo el Dr. Alvarez Chanca, ha sido para corroborar nuestras primeras palabras, que doquiera han ido tropas españolas no ha faltado asistencia médica, generosa y humanitaria.

Las condiciones estipuladas por los Reyes Católicos y el Almirante, las sabias disposiciones que se siguieron encomendando á los generales del océano los nombramientos de médicos y cirujanos, señalan los primeros albores de la medicina militar en América, y aunque sin la organización perfecta de los ejércitos del día, se mostraba á la altura de aquella época.

No dejaremos de consignar que al regresar Colón á la Española en su segundo viaje, habia perecido casi toda la guarnición que dejara en el fuerte de Navidad, figurando entre los muertos el Maestre Juan, que podemos considerar como el primer médico militar que rindió su tributo al clima Americano, pues según historiadores de crédito, puede deducirse que aquella guarnición fué diezmada por la fiebre amarilla endémica desde antes del descubrimiento.

Para terminar, conviene no echemos en olvido la gran parte más ó menos directa que tuvieron los médicos en el descubrimiento del Nuevo Mundo. Sabido es que el ilustre genovés consultó su grandiosa empresa con el físico florentino Paolo Toscanelli, el que le dirigió varias cartas sobre el particular "dando causa en gran parte á que el Almirante emprendiere el viaje con mas ánimo," según dice su hijo, Dr. Fernando.

Cuando Colón propuso á D. Juan de Portugal la empresa gloriosa que estaba reservada á la corona de Castilla, aquel monarca encomendó el estudio del negocio á D. Diego Ortiz de Calzadilla, Obispo de Ceuta, gran cosmógrafo, y á Maestre Rodrigo y Maestre Jusepe, médicos judíos á quienes él daba crédito en cosas de descubrimiento y cosmografía.<sup>1</sup>

Cuando después de varios años de inútiles pasos cerca de la reina católica, Colón se aloja descorazonado con ánimo de proponer el descubrimiento al rey de Francia, el guardián de la Rábida, Fr. Juan Perez, que de ninguna manera quiso que los reyes perdiesen la ocasión de aumentar sus dominios, detuvo al navegante en su convento y celebró junta con el físico Garci-Hernández, de la que resultó el armamento de las caravelas, siendo este modesto médico de Palos quien decidió por sus conocimientos cosmográficos al memorable Fr. Juan Perez que conocía á la reina, para que la augusta señora prestase su cooperación á la más grandiosa empresa que consignará la historia del mundo.

Mucho se ha escrito sobre estos acontecimientos con motivo del reciente Centenario de Colon. En folletos, conferencias y libros se han tratado y discutido las personalidades mas prominentes que han figurado en aquel período de la historia de España, que son páginas de la historia de la humanidad entera, pero de lamentar es que no hayan sido ensalzados como se debiera, y colocados en su verdadero lugar los médicos que prestaron su cooperación al gran navegante.

Los nombres de los maestros Juan, Alonso, Rodrigo, Jusepe, y Garci-Hernández suenan de pasada en todos los escritos históricos de esta época, pero de la biografía de estos médicos apenas se ha ocupado la posteridad, teniendo pendiente esta deuda de honor nuestros historiadores médicos contemporaneos.

Al evocar ante el gran Congreso Pan-Americano los nombres de los primeros médicos que pisaron las tierras del Nuevo Mundo, mi ánimo es que olvideis el poco mérito de mi disertación, pues necesariamente tendreis que abstraeros pensando que si mérito contrajo Colón al atravesar desconocidos mares en las frágiles caravelas cuyos diseños contemplamos hoy en las aguas del lago Michigan, no menor mérito debemos conceder á los Maestros Juan y Alonso, y al Dr. Diego Alvarez

<sup>1</sup> Estos dos físicos eran médicos de la corte del Rey D. Juan II, y tomaron gran parte en la reforma del astrolabio, sin cuyo instrumento náutico no hubiera podido intentarse atravesar el océano.

Chanca Al Almirante le guiaba la fé y confianza en su estudiada empresa, y la aspiración á una gloria cierta; y nuestros médicos iban impulsados tan solo por la generosidad en prestar sus humanitarios servicios. Saludemos pues sus nombres. Honremos la memoria de los que nos precedieron en el ejercicio de la medicina en América.

---

### (THE CLIMATE OF JAMAICA, WEST INDIES.

By JAMES CECIL PHILLIPPO, M. D.

Jamaica is an island in the Caribbean Sea, situated south of the islands of Cuba and Hayti, between and in sight of which vessels from the United States and Canada must pass in order to reach it, and is about six days' voyage by sea from New York and three from Tampa Bay or St. Augustine, in Florida. It is about 140 miles long and 49 at its greatest breadth, having safe and convenient harbors all round it, to which two or three coasting steamers make weekly visits and which fruit steamers from New York, Boston, and Baltimore are continually visiting for cargoes of bananas, oranges, pineapples, cocoanuts, sugar, rum, and coffee, dyewoods, pimento, and other tropical products. A strip of level land, several miles in breadth in some parts, lies along the coast, which is partially cultivated as sugar estates and banana and grazing properties; while the interior is exceedingly mountainous, with deep gorges and fertile valleys. The higher mountains are covered to their summits with evergreen woods and occasional coffee properties, and the lower with grazing farms, pimento walks, orange groves, and cocoa, tobacco, and ginger plantations. In fact, vegetable productions of all kinds are to be found in this island according to the altitude in which they best thrive, for while the cocoanut, sugar cane, and pineapple thrive best in the lowlands, oranges, limes, lemons, mangoes, and breadfruit do better at higher altitudes, and coffee, onions, potatoes, ginger, nutmegs, and cinnamon on higher altitudes still. Cinchona, peach, and apple trees do best on the highest lands, and the strawberries run wild as weeds. According to Mr. Harrison, the late Government surveyor, there are about 2,000 square miles of land lying along the coast, and rising to 1,000 feet of altitude; 1,451 square miles between 1,000 and 2,000 feet; 400 miles between 2,000 and 3,000 feet; 74 miles between 3,000 and 4,000 feet; 39 miles between 4,000 and 5,000 feet, and 24 miles between 5,000 and 7,000 feet; and plantations for the growth of various products are to be found in all these districts. The temperature varies with the altitude, as in all other countries, but snow is never seen even at the greatest altitude, and although ice has been found and the temperature has been at the freezing point at the highest peak, no one has been there at the time to feel it. Though the temperature varies to some extent, the daily variation is never great. The inhabitants can change their temperature environment according to their inclination or their necessities, but are not obliged to adapt themselves to the changes of temperature. Even in the highest mountains fires in the house are not really necessary. Throughout the year the variation is not greater than 17°, on an average, in the lowlands, being in the winter months about 10° lower than in the summer. Kingston is the chief town and port on the island, and is the hottest place on it. The weather reports from 1880 to 1889 give the mean daily average taken at 7 a. m. and 3 p. m. in the shade at 78°, the highest mean temperature during these years being 86° and the lowest 68°. Of course there are times when the thermometer goes up to even 94°, but such a rise is rare and lasts but a short time. On the north side of the island the thermometer on the seaboard is generally lower even than on the south, and the nights are always cooler than the days. This moderate heat

will seem strange to those who experience the intensely hot days in the Northern States, where not unfrequently the heat is much greater; but it is explained by the fact that Jamaica, being an island, is subject to the influence of the sea and land breezes. The cooler air from the sea rushes in to take the place of the hotter and rarefied air which rises from the heated land during the day, and the cool air from the land, which cools more rapidly than the surrounding sea, rushes down to take the place of the warmer and more rarefied air which arises from it at night. Thus the greater the heat of the land in dry weather the stronger are both the sea and land breezes. On an average taken for over twenty years it is found that there are not more than fifteen calm days in the year, the sea breeze generally rising at about 10 or 11 a. m., keeping up at a velocity of from 2.6 to 8.4 miles per hour until 5 or 6 p. m., when it ceases generally until the land breeze comes down at about 8 p. m. with somewhat less velocity and lasts until 7 a. m., 3 to 4 a. m. being the coolest period. The temperature decreases, too, with the elevation, a few hundred feet making a considerable difference, the barometric pressure being less. Thus within 5 miles of Kingston we find at an elevation of 300 feet a marked difference in the temperature. Ice, which is almost a necessity in the town, is by no means so there, porous jars being sufficient to make the water passably cool. At the botanical gardens, situated at Castleton, about 19 miles from Kingston on the north side of the Central Mountain range, where there is a rainfall of over 100 inches per annum and an altitude of about 1,200 feet, American tourists have not found an ulster uncomfortable in January, our driest month, and in our winter months the European troops at the military camp of New Castle at an altitude of 3,800 feet are glad to make use of two or three blankets at night. The rainfall varies considerably in different years, in different months of the year, and in different parts of the island. The northern slopes of the central chain of mountains have a much greater rainfall than the southern, the months of May, June, and October having the largest, and January, February, and March the smallest rainfall; and as tropical fevers and other diseases are most prevalent immediately after the heavy spring and autumnal rains, these latter months are the healthiest, coolest, and most pleasant of our seasons, though, as I have already shown, it can not be said that any part of the year is very hot or unpleasant, nor, as I shall presently show, very unhealthy. A reference to the observations and tables annexed taken from the last report of our Government meteorologist will, however, give in a more concise degree than I can a clear idea of these matters.

The name of the island is derived from two Indian words, Xay-mahica, meaning the land of wood and water, in both of which it truly abounds, for not only are the pastures covered with indigenous pimento and exotic mangoes and breadfruit, but its river courses, roads, and mountain sides are clothed with bamboos and palms and undergrowth of all kinds; but ferns, from the tiniest maidenhair to forests of tree ferns, are to be seen on the higher slopes of the mountains, and springs are to be found in all directions on some parts of the island, though absent in others. Of these there are several which possess valuable medicinal properties. There are hot sulphuro-calcic, warm sodic calcic, cold sulphur, cold chloride of calcium, and ferro-aluminous saline springs. Only four of these, however, are of established reputation. Of these, two are supported by the Government and managed by local boards, and one, the alumino-ferric saline, though owned by the Government, is in but small request. The one most used and most esteemed is situated under a hill near the banks of the Milk River, and is about 7 miles, by a good driving road, from a railway station about 36 miles from Kingston, and, therefore tolerably easy of access. It is a thermo-calcic saline spring, with a temperature of 92° F., and has been found especially useful in the cure of gout, rheumatism, neuralgia, and some forms of paralysis and peripheral neuritis, and is

very similar to the waters of Carlsbad and Kissengen. I have known persons suffering from gout and chronic rheumatism, unable to move from their chairs, who have been carried into the bath, and who have after three or four baths not only been able to walk and get into it, but have been able even to go and dine out with friends in the neighborhood within a week. The accommodation at this place is not very grand and the diet is not very varied, though it is good and nutritious. The bath of St. Thomas, in the east, is truly a hot sulphuro-calcic water, similar to the waters of the Eaux-Bonnes, and superior to those of the Eaux-Chaudes, in the Pyrenees, described by Pajot as being so useful in the early stages of phthisis. These springs have a temperature of  $128^{\circ}$  at their source, the steam rising from them as they run down the valley, while quite near them are cold springs, with which the hot waters are diluted for the baths. The bath-house is small but clean and comfortable, and the baths, four in number, are kept in good order, though with none of the apparatus or skilled attendance necessary to develop its healing qualities to their greatest extent. They have, however, proved wonderfully useful in the cure of gout, rheumatism, neuralgia, and cutaneous diseases, especially of a specific character, and have been and still are much esteemed. They are not so easily reached as the others and, therefore, are less visited; but as they are situated in a singularly beautiful tropic gorge, surrounded by wooded mountains, they will well repay a visitor, and he will find simple lodgings in a modest little village, with its grove of otaheite apples and spathodias near it. Begonias and ferns line the road from the village to the springs, and mango trees, breadfruit, bananas, and palms overhang it, while two nutmeg trees form the portals of the baths. The ferro-aluminous saline spring is situated at an altitude of 3,500 feet, not far from the military encampment at New Castle, the road to which lies through the far-famed fern walk. It is well worthy of attention, having a larger quantity of iron in it than some of the springs of Harrowgate, in England, which are highly esteemed, but contain no alum, and are very similar to those of a like character in Virginia. Unfortunately, they can be reached only on horseback, and there are no buildings about them for the use of travelers or patients.

In such a climate as this the wonder is that it has had such a bad reputation for fevers, but this is easily explained by recalling to mind the facts of its early history, which show a total want of ordinary care and attention to the simplest hygienic laws. In this, however, Jamaica is not singular, for older communities have suffered from the plagues, sweating fever and cholera, and many of the cities of these States, not even excepting New York, have not so very long ago suffered from epidemics of yellow fever from like causes.

Jamaica in its earliest days was colonized by troops and settlers of the worst classes of Great Britain, and was visited by the buccaneers, who spent their unlawful gains in rioting and drunkenness. The European troops were moreover located in what were at the time good strategical positions, generally in malarious and unhealthy localities, and were overcrowded in unventilated barracks; and the sailors were for months located in harbors surrounded by marshes near the embouchures of rivers, which supplied them with impure water, which they mixed with the new rum of the country. They were exposed in open boats to the heat of the noonday sun and slept after a hard day's work on the decks of their ships, or, if too drunk to get on board, on the malarious shore. The European mechanics and overseers, too, on the sugar estates were worked day and night in the fields and in the boiling and still house, had bad food and poor lodgings, and drank freely of the rum they manufactured, for they had no domestic ties and no comforts, nor care in sickness, and fell victims in large numbers to their bad habits and surroundings. But within the last fifty years great changes have taken place for the better. Yellow fever is no longer an epidemic and can scarcely be called an endemic disease in Jamaica, for a due

attention to hygienic law has led to the improvement of the towns. There are no large unacclimatized European populations, no tenement houses, closes, or wynds in which yellow fever may, by concentration, become infectious; the streets and courtyards are kept clean; and the water supply is brought down from clear mountain springs, the banks and sources of which are under police supervision. The European soldiers have been moved to higher and healthier localities and are out of the reach of low rum shops and other places of dissipation, and the sailors are better cared for than in former days. The old sailing ships which used to remain months in the ports have been supplanted by steam vessels which remain but for a few days, and the hard work of loading and unloading sugar, rum, and other articles of import or export is performed by steam winches and negroes, while the harbors and towns are kept under strict sanitary supervision.

Half a century ago, according to Brigade Surg. Maj. Mainsell, who has lately given us a brief account of his researches in the medico-military statistics of the colony, 3 soldiers out of 4 stationed in Jamaica were twice a year in the hospital, and 12 per cent died, five-sixths of them of fever; while in the last two decades we find that from 1870 to 1879 there was an average of 5 deaths per 1,000 and 13.79 admissions into hospital; from 1880 to 1889, 4 deaths and 11 admissions, and in 1889 the deaths from all causes amounted to 4, from fever none, and admissions but 11.36. In the civil population there has been the same improvement, for whereas in the early part of this century yellow fever was constantly occurring, it is now comparatively rare. During the last ten years there have been but 96 cases, of whom but 2 were passing strangers out of 16 civilians who died of it, the rest being soldiers and sailors, most of whom brought it with them or took it from those arriving from foreign ports. A strict quarantine is now maintained, and other provisions are made to prevent the introduction of epidemic diseases. Should any be introduced by any means, they can be easily isolated, and thus rendered innocuous to the community, for the acclimatized negroes, Hindoos, and Chinese are not amenable to yellow fever, nor even the white population, who, moreover, live in separate houses and are not of the class that live massed together. Phthisis of course is present, as it is in even the most favored localities in Europe and America to which its victims resort. It is not uncommon in Nice and Mentone among those who are brought up in those places. But in Jamaica it exists principally among the poorer classes, who live in unventilated and overcrowded towns, and is rare among the upper classes. The annual mortality from this disease during the last twenty years was 1.7 per 1,000 for the whole island. Kingston, which is the chief town and resort of a great number of the weak and destitute and idle from all parts of the country, supplies the largest number, while one parish which comprises a good stretch of both low and mountain lands gives a death rate from this disease of 0.8; Santa Cruz, which lies in its mountain district, having had 0 per 1,000 for several years. There are other diseases, but the mortality on the whole has not been more than 22 per 1,000 for the last few years, and but 21 in the last year and in this, 44 per cent of these being children under 5 years.

A residence from childhood in Jamaica enables me to speak with some authority on both its climate and its health, and I may therefore say in conclusion and with confidence that it offers greater inducements to the American in search of a winter resort than can be found in any other part of the world; for not only is the voyage shorter and easier, but invalids can obtain, within a radius of a few miles and of a few hours' journey from their arrival at their landing place, dry mountain situations with cheerful aspects, extensive views of tropical scenery, an invigorating, stimulating atmosphere suitable to the hypochondriac and dyspeptic, and moist mountain situations for the nervous and those who suffer from a dry and irritable condition of the air passages; dry inland and seaside situations for the

leuco-phlegmatic and those who suffer from copious bronchial discharges; saline and sulphurous baths for the rheumatic and gouty, and chalybeate springs at high elevations for the anæmic; and above all and everywhere he can, while his friends at home are shivering in close chambers, lead an outdoor life, inhaling the free air of the mountains under a cloudless sky.

*Meteorological results, etc., at Kingston, for the ten years from June, 1880, to May, 1890.*

The table above contains the results of the observations made at Kingston, Jamaica, between June, 1880, and May, 1890, inclusive. Between June, 1880, and December, 1886, the readings were taken at intervals of eight hours, namely, at 7 a.m., 3 p.m., and 11 p.m., local mean time: the daily means of pressure, temperature, dew-point, humidity, etc., were assumed to be the means of the three eight-hourly readings, but since January, 1887, the readings have been taken at 7 a.m. and 3 p.m. only; and the daily means were deduced by applying to the 7 a.m. and 3 p.m. readings their proper reductions; and from the daily means the monthly means given in the table have finally been deduced. The readings were taken with great care and regularity, and they were all corrected for instrumental errors.<sup>1</sup> In the second column the barometric pressure is of course referred to the sea level. In the seventh column the wind is stated to be southeast, and this is in consequence of the regularity of the daily sea breeze, which is almost invariably southeast at Kingston. In the eighth column the dew-point has been found from the dry and wet bulb thermometers by means of Glaisher's factors; of course, wet-bulb and tension-of-vapor columns could have been added, but it seemed useless to fill up the table with columns easily deducible the one from the other. In the tenth column the amount of cloud is given as a percentage of the whole sky. In the eleventh and twelfth columns are given for the period in question the average monthly rainfall at the public works office, Kingston, and for the whole island—the latter being deduced from about 150 stations. The remaining columns give for each month the average number of deaths in Kingston from a few groups of diseases, and the average totals; they have been taken from the returns published monthly by Mr. S. P. Smeeton, the registrar-general.

<sup>1</sup>The thermometers were exposed in the Stevenson screens over a grass lawn, 4 or 5 feet above the ground.

The following are some of the relations existing among the different columns:

*Pressure and rainfall:* If the barometric pressure be compared, not with the Kingston rainfall on account of its highly local character, but with the general island rainfall, it will be seen that a certain relation exists:  $\text{Rainfall} = 50 (30.100 - \text{pressure})$ , or, in other words, if the pressure during any month be subtracted from 30.100, and if the difference be multiplied by 50, the product will not be far from the rainfall in inches. This remarkable relation requires much further consideration, for which we have at present neither space nor time.

*Temperatures:* The mean temperature does not greatly differ from half the sum of the maximum and minimum temperatures. In order to make the agreement closer we must take into account the range, or difference between the maximum and minimum, the humidity, and the amount of cloud which covers the sky. The maxima and minima given in the table were deduced from daily readings, and their differences give the daily range; but by picking out of the original record or register the highest and lowest temperatures for each month we get the absolute maximum and minimum. To prevent confusion the absolute maximum and minimum were not inserted in the table; their averages are, however,  $4^{\circ}$  above and below the maximum and minimum deduced from daily readings. Again, in the interval between June, 1880, and May, 1890, the highest temperature was  $96.1^{\circ}$ , recorded on the 12th September, 1880, and the lowest temperature was  $56.7^{\circ}$ , recorded on the 4th December, 1887. And lastly the mean daily temperature is here given for each complete year: 1881,  $78^{\circ}$ ; 1882,  $78.2^{\circ}$ ; 1883,  $78.2^{\circ}$ ; 1884,  $77.8^{\circ}$ ; 1885,  $78.9^{\circ}$ ; 1886,  $78.2^{\circ}$ ; 1887,  $77.2^{\circ}$ ; 1888,  $78.5^{\circ}$ ; 1889,  $78.5^{\circ}$ .

*Vapor:* The humidity of the air is the ratio of the amount of vapor present to the amount necessary for saturation—saturation being taken as 100; so that humidity indirectly measures the drying power of the air.<sup>1</sup> By comparing the dew-point with the minimum temperature we see that there is an almost constant difference of about half a degree. The nights in Kingston, therefore, cool down until the temperature of the air 4 or 5 feet above the ground is a little above the dew-point; but on the ground the temperature is below the dew-point, dew is precipitated, latent heat given out, and the further fall of temperature arrested. We must now consider the connections between these meteorological results and the number of deaths in Kingston.

*Infantile diseases:* Under this heading is given the number of deaths in Kingston each month of the year from infantile diseases not otherwise specified in the books of the registrar-general. By comparing the numbers in this column with the total monthly numbers in the last column, it will be seen that the former are fairly proportional to the latter, although, indeed, their variation from their mean or average is larger. Consequently, whatever cause systematically affects the total monthly numbers, the same cause affects young children rather than adults.

*Total monthly numbers:* The total number of deaths vary on the average with considerable regularity from month to month; the maximum, 139, occurs in March; the minimum, 79, occurs in September. This variation is intimately connected with the temperature; and remembering that there must always be a considerable interval of time between such a cause and such an effect, it appears that the maximum occurs after the lower temperatures, and that the minimum occurs after the higher temperatures; or, in other words, the death rate greatly increases after our cool season, and greatly diminishes after our warm season. As in the year 1881 there were in Kingston only 5,000 white people out of a total population of 38,566, it is to the black and colored people that the above result chiefly applies; and again, as the fall of temperature during the cooler months is really very small, the large increase in the number of deaths must be chiefly due to the lives led by many of the poorest

<sup>1</sup>If the drying power of the air were measured from 0 to 100, humidity plus drying power, would always be 100.

people—to their sleeping under open sheds and dilapidated roofs; and it would therefore seem possible to reduce the Kingston death rate in the course of time.

*Fever:* There are but few deaths from this cause, and they are distributed throughout the year with considerable uniformity. One maximum occurs in July after the May rains, and another occurs in November, December, and January after the October rains. These maxima are due to malaria set free by the drying-up of the ground after heavy rains. In many countries in the tropical parts of the earth it is dangerous to disturb the soil—as, for instance, in the Gold Coast Colony in Africa—because the soil teems with malaria; and so it must have been in the earlier days of Jamaica when the land was first cleared of forests and when the soil was first turned up for the cultivation of the sugar cane; but now, we, for the most part, only feel the effect of water returning upward from considerable depths below the surface of the ground; for with the water ascend those specific disease germs which produce malarial fever when they can secure a footing in the blood and develop specific organisms.

The germs of these organisms float about in the air from place to place and gain positions enabling them to enter the blood of some animal organism, say man, where they can grow and flourish, provided they are able to successfully encounter their mortal foes, the white corpuscles of the blood. If these white corpuscles are strong and vigorous, they will overpower the foreign growth and kill it. If, on the other hand, they are weak and feeble, and the germs very numerous, the foreign growth may get a secure footing and spread luxuriantly, changing the character of the fluids of the body, coagulating, it may be, the albumin, and otherwise setting-up the unnatural and abnormal display of functions which we call disease.<sup>1</sup>

We have thus dwelt upon the cause of malaria in places which may be far removed from swamps and morasses, not on account of its importance to Kingston, but because of its widely spread influence in Jamaica.

*Lung diseases:* The number of deaths from this cause is tolerably constant throughout the year. A maximum occurs in January, and another in July; but after both these maxima there seems to be a small reaction, and the minima speedily follow.

*Dysentery and diarrhoea:* Deaths from these diseases are intimately connected with the minimum temperature; a few cold nights in Kingston are certain to produce either or both these diseases; and their virulence depends upon the extent to which the temperature falls. But some allusion must be made to predisposing causes, of which rain seems to be the most important in Jamaica; the people get wet and do not change their clothes, a cold night sets in, and disease is the immediate consequence. Thus there were rains in December, 1880, which produced dysentery and diarrhoea in January, 1881; but it was not until the cold nights of January that these diseases became serious and caused the death of 72 persons during the three following months. Again in December, 1881, and the early part of 1882 there were no rains and very little dysentery and diarrhoea. We must not expect to find complete agreement between our meteorological returns and those of the registrar-general; but we hope that the outlines of the agreement have been correctly sketched, and that the importance of the subject has been duly pointed out.

*The island rainfall:* The rainfall is now fairly well registered in Jamaica, almost entirely by voluntary observers; but unfortunately the gauges are very unequally distributed over the island. To meet this difficulty the island is divided into four divisions, and month by month the rainfall is deduced for each division, the island rainfall being simply the mean of the four divisions. It appears that while the May and October rains are everywhere strongly marked, the northern part of the island has winter rains in November, December, and January, the southern part has summer rains in August and September, and each part is further divided by the amount of rainfall, thus giving the four divisions. The northeastern division

<sup>1</sup> Nature, vol. 31, p. 267.

is cut off by a straight line drawn from Port Morant to St. Ann's Bay; it includes the lofty range of the Blue Mountains, and their continuation as the hills of St. Mary; it faces the rain-bringing winds of winter, and it has a large rainfall in November, December, and January, as well as in May and October. This division has the greatest annual rainfall. The northern division includes the parishes of St. Ann, Trelawny, and St. James. It is that part of the island which lies to the north of those broken ranges of hills which run through the center of the island in a direction more or less parallel to the Blue Mountain range. The annual rainfall is less than in the first division, but it has the same characteristics. The west central division stretches in the same direction from Chapelton to Green Island. It is deprived of the greater part of the winter rains by the two former divisions, whose hills precipitate the abundant vapor in the east-northeasterly winds; but it has well-marked summer rains in August and September, as well as the usual rains in May and October. It has a larger annual rainfall than the northern division. The last and southern division has the same characteristics as the third, but the annual rainfall is much smaller.

In the preface to Sir Hans Sloane's Natural History of Jamaica we find that he alluded to the May and October rains; to the winter rains on the north side, to the summer rains on the central hills, and to the small rainfall on the southern plains. Consequently the characteristics of the rainfall have not altered for at least two hundred years. This leads us to the consideration of the constancy of the amount of rainfall, and at length we are able to give some information on this important subject. According to the two following tables the average rainfall over the island was about  $67\frac{1}{2}$  inches for the first decennial period from 1870 to 1879, while for the second decennial period from 1880 to 1889 the average rainfall over the island was  $66\frac{1}{2}$  inches, or one inch less. But as these results are greatly effected by "flood" rains, the only wonder is that they are so nearly equal. Again, it will be seen that there has been a curious increase in the rainfall in the second decennial period in the west central and southern divisions, while there has been a larger decrease in the northeastern and northern divisions, as though the whole rainfall system had been shifted more to the south. All such variations are for the most part temporary, and the present decennial period may show just the opposite.

*The rainfall over each division from 1870 to 1889.*

## THE CLIMATE OF THE SANTA CRUZ MOUNTAINS, JAMAICA, WEST INDIES.

By JAMES HENRY CLARK, M. R. C. P.

The Santa Cruz Mountains have an elevation of 2,500 feet. The geological formation is chiefly white limestone, with a thick coating of red ferruginous earth. The climate can not be surpassed for its salutary influence on bronchitis, inflammation of the lungs, pleurisy, and rheumatism. The average maximum temperature equals 75.3°, average minimum temperature equals 66.8°, average mean temperature equals 71.1°. The rainfall is 38.25 inches; rainy days, 91. The climate is opposed to the generation as well as the evolution of tubercle in the lungs. Europeans who do not bring the germs of the disease seldom become phthisical. Those who do bring not only a predisposition but actually crude tubercle in greater or less quantity in the lung are often cured, or in the worst cases the progress of the disease is extremely slow. I am acquainted with a gentleman whose mother suffered from phthisis and died. He spat

blood on two occasions before leaving England, in 1844; he is still living, and attributes this to climate and care. One year I had on my visiting list seven Europeans and two natives, whose ages added together amounted to 751. Yellow fever is unknown, and typhoid has only occurred in two cases during the last twenty years. The roads are excellent. A post and telegraph office is accessible from 7 a. m. to 5 p. m., daily. Three churches are opened on Sundays. There is a first-class school for boys, the head master of which is a Cambridge master of arts (classical honors). There is also a school for girls. It will thus be seen that unusual educational advantages are to be found in addition to climate. The scenery is grand and the beauties of nature abound on every side. There is a large market twice a week where the delicious fruits of this country can be procured, with good beef, mutton, poultry, and fish. A sanitarium is wanted, with a resident physician, a farm, and livery stables, before patients in any numbers can be sent here. This matter is now engaging attention. I shall be glad to supply any information wanted at any and all times.

---

### THE THREE CLIMATES OF JAMAICA, BRITISH WEST INDIES; ITS COAST OR TROPICAL, TEMPERATE, AND MOUNTAIN CLIMATES; JAMAICA REGARDED AS A WINTER ISLAND FOR HEALTH.

By Dr. WOLFRED NELSON, of New York.

In this brief sketch of the three climates of Jamaica I shall follow the division laid down by the Spanish discoverers, not forgetting that although Jamaica is English now, the country was Spanish once. All who have lived or traveled in Spanish America or the West Indies will recall the old-time division of climates into, first, the *tierra caliente*, a coast, or tropical, climate; second, the *tierra templada*, or temperate climate, and, third, the *tierra fria*, or climate of the lofty mountains. Several of us have lived and practiced in the tropics, and I do not see where we moderns can improve on the old division. As in the case of all truths, improvement is impossible. M. Paul Biolley, in a recent work, refers to the three climates as three vertical zones. He calls the coast country "the hot lands," their mean annual temperature varying from 72° to 82°. The central or second region he styles "the temperate lands," since they have a mild, healthful climate, with a temperature varying from 57° to 68°; and his third zone he calls "the cold lands," including the lofty mountains, or all the land above 7,500 feet elevation, where the difference between the temperature by day and by night is great, making a climate, of course, wholly unfitted for invalids. So much may be said by way of introducing the Spanish past and the English present and future of the beautiful "Isle of Streams." We must assume that our patients are of the well-to-do classes of the coast and inland cities of America, on or near the Atlantic Seaboard, the people who are ordered off by city practitioners to avoid the long and trying winter of the north. Medical men to-day are deemed little less than walking encyclopedias. Patients must be told to take summer and winter clothing; they must be informed which are the best steamer lines, and they must be furnished with a letter of introduction to some physician in the winter resort. In speaking of Jamaica I am not dealing with the unknown. From Panama and from New York I have sent patients thither, and the excellent results in selected cases have been alike gratifying to me and satisfactory to the health seekers.

A brief glimpse of the trip from New York City may be apropos. The Atlas Line lands passengers in about five and a half days at Kingston, the capital of Jamaica. Kingston has one of the finest harbors in the West Indies. There the patient is in the coast or tropical climate; the *tierra caliente* of the Spaniards, or

the "hot lands" of M. Biolley. When he has gone ashore, a hotel or pension will be in order. Both exist. The means of the patient will determine his selection. Kingston, thanks to its far-seeing mayor, Dr. Ogilvie, is one of the best-kept and cleanest of West Indian cities. I speak after experience gained in extended travel in the islands of the various groups. The weather and climate are the things next to be considered. The mornings are cool. It is hot at noon. Soon after midday a delightful sea breeze sweeps in from the Atlantic, a life-giving breeze, Dame Nature's own champagne. The evenings are pleasant and the nights are cool enough for restful sleep. Kindly bear in mind that I am dealing with the period recommended to the health seeker, from November to April, or the months so trying in these latitudes to all in impaired health. I assume, as a matter of course, that no seeker for health will visit any health resort, be it where it may, unless under medical advice. Many without skilled advice simply hasten the end, and rush off to die amid strangers. What are our patients to do in Kingston? Mental recreation they must have while the climatic cure is in order. Kingston has an estimated population of 60,000 people. There are four ably-edited daily papers furnished by cable with the news of the world. Public buildings, churches, and all that we moderns deem so essential to our artistic existence are to be found within the city. Lovers of nature will find her delightful pages open and ready for interpretation at every turn in any of Jamaica's three climates. Those of a scientific turn of mind and lovers of books can both satisfy their respective longings; all can easily find the mental distraction requisite while mind and body are obtaining needed rest.

Those who are to make a stay in the city will naturally like a change occasionally. What shall it be? Delightful and instructive trips may be made around the coasts of Jamaica by steamer, a journey of some 500 miles, the voyager visiting more than twenty ports and enjoying a succession of tropical vistas. Carriage tours may be made on the coast levels. Jamaica is famous for her perfect roads. To those from the north all will be new and highly attractive. A stay at the Constant Springs Hotel, some 800 feet above sea level, will be a pleasant change. The hotel is situated on a fine plateau some 6 miles out of Kingston, beyond the village of Hay-Way Tree. It is a large building, especially made for winter visitors, and substantially built of stone. It has the all-around galleries that are so comfortable and pleasant, offering a magnificent view as well as restful shade. There one can sit and feast his eyes on the varied tropical scenery made possible by the three climates of Jamaica. Below is the city of Kingston; beyond it stands old-time Fort Augusta, a Spanish souvenir. Close at hand are the foothills; above them Newcastle, a mountain camp, nearly 3,000 feet above sea level, and towering over all are the lofty Blue Mountains, whose peaks rise for 7,000 and 8,000 feet above the sea. Many delightful outings may be devised for pastime, such as picnics to the hills or trips to the city or to the Government Gardens. In the cool of the morning exercise may be taken on foot. With horses and carriages there will be no lack of variety. At the Constant Springs Hotel the guests are in a land of sunshine, with an average temperature of say 80°. Leaving there, let us go into Kingston and take the railway to the mountains, going there by carriage to the hotel at Moneague, built and opened in 1891 as a "hill resort;" a locale, in a climatic sense, midway between the coast and the mountain level at Mandeville (of which more anon). I found the hotel there good, suited to its purpose, with rooms well ventilated. The building has lower and upper balconies, delightful lounging places where the weary can rest body and mind and be content. The drive from the hotel to the railway, when it is taken early in the morning, is a wonderful experience. In the early hours the peaks pierce the masses of fleecy clouds that hide the scenery below. Looking down from the upper levels of the "divide," a Canadian will fancy the cloud masses to be a huge snow-covered plain. I have

made two trips to Jamaica. Limitations of time prevented me from visiting Mandeville. For my information regarding it I am indebted to the Hon. George Solomon, with whom Mandeville and the Santa Cruz Mountains are favorite themes. Mandeville is a mountain village some 2,000 feet above the sea level and just within Jamaica's second, or temperate, climate. On a clear day the view from Mandeville is wonderfully fine. The distant ocean can be seen, a vast sheet of blue, closed in by the horizon. Mandeville is within easy reach of Kingston, part of the way by rail and the remaining 6 miles by carriage. There are a number of boarding houses and a hotel. Arrangements for Mandeville should be made in advance. Jamaica represents a wealth of tropical scenery. Its variety gives it a special charm. Many patients require so much distraction that a suitable climate alone is not sufficient for them. Many of the nervous class must think of other matters and be forced into exercise and recreation. Exercise without fatigue should be the order. To the medical mind such exercise means much; tissue change, rest, repair, new strength, increased appetite, sounder sleep, and a greater capacity for enjoyment. Such a course in neurasthenia generally means cure, or what Dr. Linn in his book terms the "climatic cure." I have referred to two of the three climates of Jamaica. Those who are sufficiently well can investigate the third and "do" the lofty mountains. A day may come when sanatoria will be found in them, but for the purposes of our patients we must be content with two climates, leaving the third for convalescents and tourists.

M. Stern, M. R. C. S., England, L. R. C. P., London, in an excellent article on the climate of Jamaica,<sup>1</sup> refers to the seasons of the island as "two rainy and two dry seasons, one in May and one in October, lasting for about two months, the intervening periods being known as the dry season. From December to the end of April the weather is fine and dry." He adds:

In estimating the fitness of this or that climate, where it becomes a question of choice of residence for an invalid, barometric pressure and amount of moisture are also important factors in the calculation. The more equable the temperature, the lighter the air, the less the barometric pressure (always, of course, with certain limits), the clearer the sky, the more favorable are the climatic influences.

Dr. Stern quotes Dr. Lincoln, an American writer, thus:

It is now admitted that the most general test of the value of a climate consists in its suitability to be lived in, or, if this seems like tautology, the best climate is that in which a delicate person can be out of doors with comfort and safety for the greatest number of hours and days in the month. This requirement can be fulfilled in most cases only by the combinations of clear sky (sunlight), warmth (not of the rays of the sun but of the lower level of atmosphere), and equability or freedom from violent changes of temperature and chilling winds.

To quote further from Dr. Stern's extended experience as a practitioner in Jamaica:

Now, here, sunlight is abundant, equability is unquestioned, and in the higher lands there is the element of stimulus (which is, perhaps, somewhat wanting at the lower levels). Air stimulus is important in association with equability. The moisture, besides not being excessive, has this advantage, that it interposes a protective screen from the intense solar rays. Thus, sunstroke, so common an occurrence in New York, is, even in the hottest and most sultry day of exceptionally severe seasons, almost unknown. Exposure to the midday sun is, nevertheless, always to be avoided, especially by newcomers.

Dr. Stern rightly classes the climate as a sedative one, and while noting that such a climate may not be the best for all pulmonary cases, he adds:

For the catarrhal variety (of consumption) so common in England and America, such a climate is eminently beneficent, and we believe it will be found that it is mostly this form which has so wonderfully improved here. The genial warmth, the free ventilation, the light, the freedom from close rooms, the little chances of

---

<sup>1</sup> Handbook of Jamaica, 1881.

getting chilled, all contribute to this end. Perhaps we might venture to say that for all cases of incipient phthisis it is all that could be wished, arrest of the progressive symptoms being most marked.

Dr. Stern then passes on to review the springs of Jamaica, the curative waters of which are historic:

There are several mineral springs on the island. The two principal are, one in Vere, 50 miles from Kingston, the other in the pretty village of Bath in St. Thomas. The waters of the first are useful in gout and rheumatism. In this respect they will rival most if not all of the famed thermal waters of the Continent or even Buxton in Derbyshire, which we believe to be even more beneficial than Aix les Bains in Savoy, Baden Baden, or Wiesbaden.

The results of analyses of the waters in Jamaica have been published recently in a book issued by the Government of the island. The title of the book is, "Jamaica at the Columbian Exposition." The article referred to describes the springs, the climate, etc., and is from the pen of Dr. Thomas L. Stedman, of New York City. It appears also in Buck's Reference Handbook of the Medical Sciences. On page 84 of the book first mentioned Dr. Stedman mentions the following springs: (1) Milk River Bath, (2) St. Thomas the Apostle, (3) Jamaica Spa, (4) Silver Hill Spring, (5) Manatee Bay Spring. The first of these is a thermal sulphur spring, the second chalybeate, and the third a thermal saline spring.

Dr. William Osler, in his book,<sup>1</sup> describing a suitable climate, fully indorses the views held and advanced by Dr. Stern in 1881. Dr. Osler epitomizes the matter thus:

The requirements of a suitable climate are a pure atmosphere, an equable temperature, not subject to rapid variations and a maximum amount of sunshine. Given these three factors, it makes little difference where a patient goes, so long as he lives an outdoor life.

Dr. T. M. Coan, of New York, in his introduction to Dr. Linn's work, *The Health Resorts of Europe*,<sup>2</sup> summarizes the subject in happy phrase, as follows:

The very pleasurable of health resorts, in fact, conspires with the scientific methods of therapeutics. The happy mind and the healthy body are correlatives. Watering places combine in a measure heretofore unknown the strictly curative arts with the means and appliances which go to make up cheerful daily existence. Whether in the beauty of the mountain solitudes or the stir of a crowded and sociable resort the philosophy of cure is the same, to combine the most approved methods of science with agreeable social and spiritual conditions. Under such conditions the tour and the cure are coincident.

In closing I can only reiterate a statement of my own, made some months ago:

Jamaica's greatest wealth is her perfect winter climate. A visit will reveal her grand and classic scenery, and her climatic advantages as a winter island for health are of the highest order.

## LES MESURES PROPHYLACTIQUES CONTRE LES ÉPIDÉMIES

Par le Dr. J. B. DA LACERDA de Rio de Janeiro, Brésil.

Voilà un sujet, qui, je le sais bien, va attirer beaucoup l'attention du Congrès. Le Brésil et les États-Unis sont si rapprochés maintenant par une communauté d'intérêts économiques et sociales, que ces deux grandes républiques américaines ont le devoir d'accorder des mesures sérieuses dans le but de se défendre contre l'importation de certaines maladies pestilentiellles.

À mon point de vue, la question est assez difficile et complexe: elle exige une longue discussion et beaucoup de réflexion. Au milieu des opinions diverses, soutenues par les représentants de tous les pays de l'Amérique, envoyés au Congrès,

<sup>1</sup> Practice of Medicine, New York, 1892.

<sup>2</sup> New York, August, 1893.

il sera sûrement difficile, dans un délai très court marqué aux réunions, d'arriver à des conclusions précises, tout-à-fait pratiques, concernant les mesures prophylactiques contre l'importation du choléra et de la fièvre jaune.

Malgré tout, nous sommes encore aujourd'hui en faveur des quarantaines. Seulement il faut bien s'entendre sur l'application pratique de cette mesure, aussi bien que sur les détails. Ceux-ci ont une importance assez considérable, et c'est parce qu'ils ont été souvent méprisés que les quarantaines ont été accusées d'inutiles.

Au Brésil où la fièvre jaune s'est fixée depuis longtemps, nous n'avons qu'à nous défendre contre le choléra.

Eh bien ; grâce aux mesures de défense bien prises et rigoureusement exécutées ici par une autorité sanitaire énergique et consciente de leurs devoirs, nous avons eu, il y a huit ans, le bonheur d'échapper aux ravages du choléra.

Du sein du Congrès Pan-Américain on pourrait bien faire sortir les bases d'une convention sanitaire, dont les prescriptions fussent respectées par toutes les nations de l'Amérique.

Ce serait, à mon avis, un des plus grands services qu'on aurait le droit d'attendre d'une si remarquable assemblée de médecins éminents.

---

#### BASES GENERALES QUE PODRÍAN PROPONERSE Á LOS DIVERSOS GOBIERNOS DEL CONTINENTE AMERICANO, PARA HACER UNIFORME Y EFICAZ LA POLICÍA SANITARIA MARÍTIMA INTERNACIONAL.

Por el Dr. EDUARDO LICÉAGA,

*Presidente del Consejo Superior de Salubridad del Distrito Federal de México.*

El continente americano bañado en toda su longitud por los dos océanos, tiene que comunicarse con las otras partes del mundo por la vía marítima. Si por ella reciben millares de pobladores todos los productos de la industria y de las artes que han llegado á un alto grado de perfección en el Viejo Mundo, también ha recibido ya las enfermedades que transportan los hombres y las mercancías ó los gérmenes que las originan y que de tiempo en tiempo han sembrado en los pueblos del nuevo continente el luto, la desolación y la ruina.

El sentimiento de la conservación obligó á cada una de las naciones americanas á rechazar las epidemias ; inspirados unos pueblos en el terror y otros en la experiencia adquirida en los del antiguo continente, ó cerraron sus puertas á procedencias de los lugares infectados, ó impusieron prolongadas cuarentenas y severas restricciones á los buques que procedían de aquellos.

Para la adopción de estas medidas, no sé yo que haya habido más acuerdo especial que la convención de Lima del año de 1888 y el Congreso Panamericano de 1889. Pero los incesantes progresos de la ciencia nos imponen la obligación de proponer nuevas bases para los convenios futuros y nunca se ha presentado ocasión más propicia para estudiarlos, que la presente en que se reúne un congreso formado por los representantes de las naciones del continente americano interesadas en la resolución de esas cuestiones.

El acuerdo sobre este punto es enteramente necesario para atender á los intereses de la salubridad y del comercio : cuando no se ha llegado á él, como en el año pasado, que el cólera amenazó invadir el continente, Nueva York estableció una cuarentena de veinte días, Panamá la extendió á un mes y alguna de las Repúblicas sudamericanas hasta seis semanas, en tanto que México había reducido la suya á cinco días. De esta desigualdad, resultó que los buques se retiraron de los puertos en donde se les esperaba larga demora ó transportaban sus pasajeros y mercancías

tal vez infectadas, á otros buques que venían de puertos indemnes y que amparados por su patente limpia, podían llevar el contagio á naciones, que como la nuestra, habían disminuido el rigor de sus restricciones en beneficio del comercio.

El modo de proteger el continente americano, es que cada una de las naciones que le componen, en obediencia de sus propios intereses, procure la defensa de su territorio.

Un conocimiento más exacto de la duración que ordinariamente tiene el período de incubación del cólera, permite reducir á cinco días la observación de las personas que se sospeche puedan llevar el germen de la enfermedad; esta observación ha permitido confirmar, una vez más, que las deyecciones de los enfermos y las ropas y objetos que han mancillado, son los propagadores de la enfermedad, pero que no lo son las ropas limpias, ni la correspondencia escrita, ni los periódicos, ni los libros, ni las mercancías que no se hayan contaminado. La experiencia ha confirmado que el agua es un vector de los gérmenes de la epidemia. Estos datos de la experiencia permiten proporcionar á sus verdaderos fines el aislamiento de los enfermos, la desinfección de los objetos contaminados y la purificación del agua, poderosos recursos con que cuenta la ciencia sanitaria actual para impedir la introducción de una enfermedad transmisible ó detener su desarrollo.

El aislamiento de los enfermos ha de ser completo á fin de que este sea un medio eficaz de impedir la transmisión de la enfermedad. La desinfección, para llenar este mismo fin, ha de destruir los gérmenes que se encuentren en los objetos mancillados por las deyecciones de los enfermos. Estos son los principios; la manera de aplicarlos es variable.

Así por ejemplo, una nación realizará el aislamiento en un lazareto modelo, la otra en un hospital que ha apropiado á este uso, la de más allá en barracas provisionales y alguna habrá que establezca en un pontón su hospital de coléricos; pero todas harán el aislamiento completo y lo prolongarán el tiempo necesario para que sea eficaz.

Perfeccionadas como lo están ahora las reglas para hacer la desinfección, bien definidos los objetos á los cuales se ha de aplicar, y muy reducido su número, podrán ser convenientemente utilizadas por todos los países de América. En unos se hará con la amplitud con que se hacen en Charleston y Nueva Orleans, en grandes instalaciones que pueden tomarse como modelo; otros, como México y la República Argentina, lo harán por medio de estufas de menores dimensiones, en las que se utilizan, para la destrucción de los gérmenes, á la vez el calor y la presión; en algunos se emplearán las cámaras en donde se produce el ácido sulfuroso por la combustión del azufre, y otros emplearán los aparatos portátiles que pulverizan la solución de bicloruro de mercurio, para impregnar con ella los objetos infectados; pero todos inspirados en los mismos principios científicos y aplicándolos con las reglas que ha establecido la experimentación, llegarán al fin deseado—destruir los gérmenes que propagan las enfermedades.

Un personal instruido en las operaciones de desinfección y convencido de su eficacia y de la del aislamiento para evitar la importación de las enfermedades transmisibles, será el ejecutor de las disposiciones sanitarias. Conforme á las instituciones de cada nación, ese servicio dependerá del Gobierno General, como sucede en México y como comienza á verificarse en los Estados Unidos del Norte, ó dependerá de los Estados que forman una república, ó de los municipios.

Mas para obrar en armonía, no basta estar de acuerdo con los principios científicos y las reglas de su aplicación; se hace además necesario convenir de una manera general, en la clasificación que se haya de dar á los buques, según su estado sanitario y á las mercancías según se encuentren ó no mancilladas. Desearía entrar en los detalles de esta clasificación para exponeros las razones en que se funda su conveniencia y para demostraros sus ventajas, pero temiendo ocupar demasiado el precioso tiempo que destinaís á tantos estudios de importancia, me

limito á pedir que las naciones americanas propusieran á sus gobiernos la aplicación de medidas precautorias contra el cólera, que son ya uniformes en el continente Europeo, merced á la sanción que han recibido de los Gobiernos las conclusiones aceptadas en la Convención de Dresde.

Las proposiciones que tengo la honra de someter á la deliberación del Congreso, son las siguientes: (1) Uniformar la duración de la cuarentena, proponiendo que sea de cinco á siete días después del último caso de cólera habido á bordo. (2) Señalar en el litoral de cada nación cuál ó cuales puertos se consideran apropiados para hacer el aislamiento de los enfermos. (3) Establecer en esos puertos, lazaretos, hospitales ó casas de asilo destinados al aislamiento. (4) Indicar en cada país y en cada puerto de su litoral, cuales son los procedimientos de desinfección que acepta y en que forma los aplicará, para que las demás naciones sepan si pueden contar con una perfecta desinfección en esos países. (5) Hacer la declaración de que existe uno ó más focos de epidemia en una nación, dándolo á conocer á las demás por medio de sus agentes diplomáticos ó consulares. (Los casos aislados no se consideran como focos de infección.) (6) Indicar en la declaración de qué manera comenzó la epidemia, la marcha que ha seguido, el número de casos comprobados clínicamente y el de defunciones, y por último, las medidas que se han tomado para impedir la extensión de la epidemia. (7) Declarar las medidas que un Estado va á adoptar respecto á las procedencias de un territorio contaminado. (Este es uno de los objetos capitales de la uniformidad en los procedimientos.) (8) Se debe entender por territorio contaminado, aquel en que existan focos de epidemia colérica y solo á él se referirán las medidas de precaución. Se considerará como sano aquel territorio que no tenga actualmente foco epidémico aún cuando haya existido, siempre que hayan transcurrido cinco días después del último fallecimiento de que se tenga constancia oficial y á condición de que se hayan ejecutado las medidas apropiadas de desinfección. (9) Conforme á las Conferencias de Venecia y de Dresde, dividir los buques, según su estado sanitario, en tres clases, como sigue: Infectados, Sospechosos é Indemnes; considerando como infectado al buque que al llegar al puerto lleva enfermos á bordo ó los ha tenido en los últimos siete días de navegación; como sospechoso al que ha tenido casos de cólera en el momento de la partida ó durante la travesía, pero en el cual no se ha presentado ningún caso nuevo durante los últimos siete días de navegación; indemnes, aquellos que no han tenido defunciones por causa del cólera ó casos de la misma enfermedad al salir del puerto, durante la travesía ó á su llegada, aun cuando procedan de puerto infectado; pero siempre que la travesía haya sido de más de siete días. (10) Adoptar para el tratamiento de estas tres clases de buques las medidas aceptadas por la Convención firmada en Dresde el 15 de Abril del presente año. (11) Adoptar las cláusulas de ese mismo Convenio Internacional en lo que se refiere á las mercancías ú objetos susceptibles, bajo el punto de vista de su desinfección, de su tránsito por territorios sanos ó contaminados y de la prohibición de importarlos á los países que se trata de defender. (12) Las cartas, correspondencias, impresos, periódicos, papeles de negocios y libros no se someterán á ninguna restricción cuarentenaria ni á desinfección.

## ON THE CLIMATE OF EGYPT IN GEOLOGICAL, PREHISTORIC, AND ANCIENT HISTORIC TIME.

By J. A. S. GRANT (BEY), A. M., M. D., LL. D., of Cairo, Egypt.

## CLIMATE OF EGYPT IN GEOLOGICAL TIME.

In treating of the climate of Egypt in geological time very naturally you will expect me to take you back along the thread of geological history to that period when the nebulous mass of this globe (thrown off during the formation of the solar system) took on somewhat of a definite shape and had already laid the foundation of its present crust. It would seem that the primitive waters of ancient mythology and tradition, during the contraction of this shapeless, nebulous mass, formed a universal sea of water with a universal sea of steamy, vaporous atmosphere above it, which entirely obscured the sun, although it was much larger and nearer then than now. At this period darkness covered the face of the deep and the climate must have been very hot and very damp, but there was nothing as yet to make it malarious, for no vegetation could have existed at this period. As the cooling process continued the misty steam that filled the atmosphere would in time take on more of the nature of clouds suspended in the air, thus permitting the direct rays of the sun to penetrate here and there so as to light up the primitive waters that now enveloped the central mass of this globe. During the formation of these waters the excessive heat had caused to be dissolved in them many of the primitive elements of our earth, which, as the water cooled, were slowly deposited in crystalline form and made a solid bottom for this primitive and still comparatively hot and shallow sea. In the upper stratum of this deposit Sir William Dawson has discovered the fossil remains of a species of *Foraminifera*, showing that the climate had so far changed as to allow of the existence of at least a low type of animal and vegetable life. The origin of such life does not come within the scope of this paper, as we have only to deal with things as we find them and draw our inferences as to the kind of climate that would allow of their existence, modification, or extinction. As shrinkage went on, owing to the continuance of the cooling process, the rocky bed of the sea would become crumpled up here and there from the external pressure, causing the shell of the earth to fall in. Thus projections of crystalline rocks would appear above the surface of the water and form the first dry land as islands, or even continents, in this vast sea. Sir William Thompson says the past age of the sun can not have exceeded twenty million years. This reduces the whole geological time of this earth since the formation of the crystalline (Laurentian) rocks to a period of about six million years. No doubt at different places in the inside of the crust of the earth we should also find at this early epoch pressure from within caused by igneous action, forcing up the crystalline shell at some places and even bursting it at others, causing geysers, burning mountains, and granite formations.

The first appearance of Egypt, some six million years ago, was in the neighborhood of Assouan, where we have both the above geological formations peering through the Nubian sandstone, viz, the primitive crystalline rocks intersected by igneous formations or granite. These rocks, now exposed, were being continually washed by a hot, shallow sea, while they were acted on at the same time by drenching rains, thus causing their slow disintegration, the débris of which settled at the bottom of the sea and formed the geological stratum known in our day as the Nubian sandstone. After a period of geological time the Egyptian part of the crust of the earth was still more upheaved, exposing a larger surface above water and laying bare a great deal of the Nubian sandstone that had been deposited at the bottom of the sea. The climate was still damp and very hot. All through the rest of the primary formations, and extending to nearly the end of the

secondary geological period, Egypt lost in area instead of gaining, for the more than tropical rains continued to disintegrate the rocks and washed the greater part of the Nubian sandstone into a sea, which was becoming more and more animated by animals that were rising in the scale of existence, and which was depositing, layer upon layer, at its bottom an illustrated history of its inhabitants and its work. Toward the end of the secondary geological period Egypt, Arabia, and Palestine appear as three rocky islands with fringing belts of sand. At this time the eastern part of the island that represented Egypt became submerged, and on it, at the bottom of a still very warm sea, a Cretaceous deposit took place, inclosing in its substance the remains of animals of a much higher type of organization than we have yet met with. Some of these animals were amphibious, so that they could come out of the water and bask in the sun on the sandy shore of the sea. They are all representatives of animals of a warm climate. The Tertiary period was ushered in by a general, though unequal, submergence of all that is known of the Egypt of the present day, except the region about Assouan, which continued to appear as a rocky island in the Tertiary sea just as it had done in the primary and secondary seas. During the deposit of the lowest stratum, called "Eocene" (nummulitic), of the Tertiary geological formation the geographical position of Egypt was still occupied by a comparatively warm sea, as shown by the fossils<sup>1</sup> that are now found in what must have been its bed. In due time the crust of the earth was pushed up out of the water by volcanic action<sup>2</sup> and became dry land. After a space of geological time alluvium was formed on the now exposed Eocene stratum and vast forests grew<sup>3</sup> that must have been well watered in the ordinary way by the rains of heaven. Naturally there would be a watershed somewhere, and therefore a river. This condition of things must have lasted many thousands of years, when another volcanic disturbance or natural shrinkage took place and a portion of this part of the globe became again the sea bottom. The alluvium was all washed away, leaving only sand and fallen, decaying trees, water-logged in a silicious sea, which was rendered all the more silicious by the presence in it of geysers. As the sea cooled down the trees became silicified, and lay like rocks embedded in the sand<sup>4</sup> at the bottom of the sea, while in the immediate vicinity of the geysers themselves the loose sand became solidified into a heterogeneous mass, containing many of the silicified trees in the lowest part of its structure. Some of the trees are palms,<sup>5</sup> showing that Egypt continued to have a tropical climate similar to that of the Soudan of our time. This new stratum formed what is called the Miocene,<sup>6</sup> and when it in turn was upheaved<sup>7</sup> and

<sup>1</sup> One of these fossils was presented by me to the late Prof. Sir Richard Owen, who described it fully in the Quarterly Journal of the Geological Society for February 7, 1875. It proved to be the fossil brain of an Eocene Sirenian mammal, of the same type as the dugong which still exists in the Red Sea.

<sup>2</sup> There is abundant evidence of volcanic action in various parts of Egypt. Near Cairo, at the cataracts, and along the Red Sea coast Plutonic rocks are met with.

<sup>3</sup> These forests contained exogenous and endogenous trees. Several species of the exogenous ones have been classified, and a species of the endogenous tree has also been discovered. It has been described by the late Sir Richard Owen as being "undoubtedly palm," but it has not yet been further classified.

<sup>4</sup> The sand was formed ultimately from the crystalline rocks of the interior and proximately from the waste of the Nubian sandstone and the sandy upper Eocene beds. The thickness of the Miocene sandstone stratum would be about 100 feet. (Dawson.)

<sup>5</sup> These forests contained exogenous and endogenous trees. Several species of the exogenous ones have been classified, and a species of the endogenous tree has also been discovered. It has been described by the late Sir Richard Owen as being "undoubtedly palm," but it has not yet been further classified.

<sup>6</sup> The sand was formed ultimately from the crystalline rocks of the interior and proximately from the waste of the Nubian sandstone and the sandy upper Eocene beds. The thickness of the Miocene sandstone stratum would be about 100 feet. (Dawson.)

<sup>7</sup> The igneous rocks at Abou Zabel, about 11 miles north of Cairo, belong to this period, or perhaps even a little later. (Dawson.)

became dry land all its loose sand was gradually blown away, leaving the Eocene towering up at places to the height of 600 feet, as the Mokattam range at Cairo, while the petrified trees were exposed lying on the surface of the Eocene. Of course where the sand itself was glued together by silica it remained as sandstone hills, such as "Gebel Ahmar" near Cairo, where traces of two geysers may still be seen and petrified wood embedded in its lower stratum, thus showing, as if it were written on the pages of a book, the exact position in geological history to which the petrified trees belong and the climatic conditions of that period when these natural forests existed. The areas of marine Miocene, however, in Egypt are rare, indicating that this region had already assumed in a great measure a continental character.

According to Sir William Dawson, at the close of the Eocene period the Gulf of Akabah, which had been up till then in communication with the Mediterranean, was closed, but the Gulf of Suez continued to be a strait, and the Mediterranean, which washed the base of the Mokattam range, extended even to the east of Gebel Attaka on the Red Sea. This remained so all through the Miocene period, so that there was free communication between the Red Sea and Mediterranean, and the disconnection could scarcely have taken place till the first continental period of the Pliocene, when the Blue Nile lost itself in a lagoon of the isthmus on the Red Sea side and contributed considerably to the enlargement of that isthmus. This was the first separation of the waters of the Red Sea and Mediterranean in geological history. The climate was then a little warmer than now, as may be gathered from the shells and animal remains of the Pliocene formation. The Pliocene age was probably more continental than the Miocene period. After this came the great Pleistocene submergence (about twenty thousand years ago), when the Red Sea and Mediterranean again intermixed freely for a short geological period, while the present valley of the Nile (without any Nile) was a long fiord of the sea stretching as far inland as the rocky barrier at Assouan and being gradually deepened by the erosive action of the sea. The raised beaches<sup>1</sup> near Cairo belong to this period, and the scattering of bowlders from the eastern crystalline mountains over the Libyan Desert seems to imply the action of floating ice<sup>2</sup> in some part of the Pleistocene period. The softer parts of the Miocene sandstone must also have been wasted away at this time. This was succeeded not long after by a reëlevation, partially restoring the conditions of the first continental period and finally connecting Asia and Africa by a permanent isthmus. A divergence is now manifested between the fauna<sup>3</sup> of the Mediterranean and Red Sea, the fauna of the Mediterranean taking the type of the Atlantic and that of the Red Sea the type of the Indian Ocean, showing a complete change between the climates of these two regions. The oldest part of the isthmus is the Miocene bed at Shaloof, about 13 miles from Suez and only 6 to 9 feet above the level of the Red Sea. This bed is covered in part by the old Blue Nile deposit of the Pliocene, or, as some geologists contend, of the later Pleistocene, both these having the continental periods, with an abundant rainfall. The highest parts of the isthmus are at El Gisir to the north and at Serapeum to the south of Lake Timsah. These elevated portions of the isthmus are composed of the old Nile deposits. Thus the ancient Blue Nile built up a considerable portion of the isthmus at a time when the climate was warmer than at present, for this limestony stratum, extending from El Gisir to Shaloof and stretching east and west, contains fresh-water shells that are now confined to the

<sup>1</sup> At Het el-Qorab hill, a little to the south of the Great Pyramid and at an elevation of 40 feet above the plain, there is an old sea beach of the Pleistocene period.

<sup>2</sup> Sir William Dawson inclines, however, to the water rather than the ice agency. In fact, there is no trace in the geological history of Egypt of there ever having been the cool summers necessary for the formation and continuance of a glacial period.

<sup>3</sup> At the present day the shell fish of the Red Sea are quite distinct from those of the Mediterranean.

Upper Nile and that have somewhat of a modern character as compared with what we might expect in a Pliocene bed. In the later Pleistocene it would appear that the Blue Nile and Jordan debouched into the same lagoon of the isthmus, which at that time of continental elevation was much more extensive than now. It is to this period that we must ascribe the Sahara Sea and the large inland sea<sup>1</sup> of Geikie which included the Black Sea and Caspian and a large tract of country to the west of the Ural Mountains. As long as these large bodies of water existed the rainfall in Egypt and Arabia must have been excessive, and this accounts for the manner in which the surfaces of the anorthosite greiss or diorite and schist show such an amount of wasting and disintegration. Prof. Hull has also found evidences of a chain of ancient lakes in the Sinaitic Peninsula that must date from this period, and that disappeared when these inland seas dried up and the rainfall ceased. At the close of the Pleistocene elevation, or, in other words, in the early modern geological epoch, we find the Red Sea shells at the Bitter Lakes quite like the recent shells. The ridge at Shaloof must have been at this time under water, as we may judge by the shells now to be seen in its upper layer. Its elevation,<sup>2</sup> therefore, is quite modern, geologically speaking, and the elevating process continues, though slowly as measured by the geological clock. At a date more immediately preceding the prehistoric<sup>3</sup> period the land of Egypt was higher than at present, but owing to the earth's shrinkage the whole country sank considerably, thereby causing two fractures that are evident, one along the Mokattam range from Cairo to Suez and the other along the present valley of the Nile, whereby a depression of upward of 150 feet on the Libyan side took place. This convulsion of nature was so extensive as to divert the White Nile from being a confluent of the Congo and the Blue Nile from flowing into the Red Sea; and it caused these two rivers to unite to form the present Nile and flow down its present bed to debouch in a shallow gulf of the Mediterranean Sea, which had already retired from Assouan to a little above Memphis. Even at the present day, were the Nile to dry up, the sea would again reach this ancient limit (Memphis) along the empty bed of the river.

#### CLIMATE OF EGYPT IN PREHISTORIC TIME.

The prehistoric period of Egypt was ushered in by the formation of the present Nile and the fluvial deposits that have made the country rich and habitable. This took place only about 8,000 or 9,000 years ago.<sup>4</sup> The Nile, however, did not find its way to the Mediterranean without encountering formidable obstacles in the shape of crystalline rocks, granite and sandstone dikes, and calcareous beds, which one by one were either swept before it at once or else the pent up water formed large lake districts and overflowed the obstacles as cataracts. Most of these have become gradually rubbed down<sup>5</sup> and form now only rapids. Some of them, however, were broken through suddenly, causing a regular deluge in the lower country; and several of these floods must have taken place in historic times, for when Solon visited Egypt, about 600 B. C., and asked the Egyptian priests if they had in their history any mention of the universal flood, such as is

<sup>1</sup> It must have been during the existence of this sea that it was possible for the Mammoth to live in Siberia, as such a large sea must have modified the climate in its vicinity and thus made Siberia more habitable than it is to-day.

<sup>2</sup> In Strabo's time, 24 B. C., the Red Sea extended to the north end of the Bitter Lakes, and that only by means of a canal, originally dug by Darius Hystaspis (520 B. C.) from south end of Bitter Lakes to Red Sea, about 10 miles in length.

<sup>3</sup> Prehistoric as far as Egypt is concerned.

<sup>4</sup> The depth of the Nile deposit across the delta in the latitude of Zagazig was ascertained, by means of a series of borings in 1883, to be between 30 and 40 feet; and as authorities are agreed that the rate of deposit is between 4½ and 5 inches in a century we thus find that the convulsion of nature referred to in the text must have taken place about the time stated.

<sup>5</sup> In the whole of the Nile valley from Edfore northward the geological formation is calcareous (Eocene), which the Nile has scooped out to the depth of 200 feet.

recorded in the Greek history,<sup>1</sup> they replied that they had records of several floods, no doubt referring to the sudden giving way of cataract barricades. The first obstacle to yield to the ever-conquering water in the prehistoric period was the sandstone dike at Silsilis, a few miles (40) to the north of Assouan. At this time the ancient Ethiopia, commencing at Assouan, was, in a great measure, under water, as the cataracts at Assouan and Semneh (near Wady Halfa) had not yet been worn down, nor had they given way. The same, no doubt, may be said of many of the other cataracts that simply made the Nile valley a series of lakes, while at the same time there was a large inland sea where the Sahara is now. These vast sheets of water, under a tropical sun, must have made the neighboring countries quite rainy, and amply account for the abundant evidences we have that the Nile at this time had a larger volume of water than it has now, and was fed by local rains and streams that rushed into it like so many Niagaras. (Petrie's *Ten Years Digging in Egypt*.) Prof. Sayce tells us (*Ancient Empires in the East*) that the wadys and cliffs on each side of the Nile valley are water worn and covered with boulders and pebbles which bear witness to the former existence of mountain torrents and a considerable rainfall; and the discovery of Palæolithic implements near the little petrified forests and in other places makes it clear that some of the geographical and climatic changes the country has undergone have taken place since it was first inhabited by man.

#### THE CLIMATE OF EGYPT IN ANCIENT HISTORIC TIME.

As we advance to the historic period which has been characterized by the deposition of much fluviatile sediment, especially in the Delta, and probably by a slight depression<sup>2</sup> of the Mediterranean coast, accompanied by a slight elevation from the latitude of El Gisir southward, we find that the primitive prehistoric immigrant tribes that had come from a northern region and had settled as independent colonies all along the valley of the Nile were in time subjugated by another and a stronger race<sup>3</sup> coming from the east, or land of Poun-t.<sup>4</sup> It is only now that we find anything like a concentrated government and the establishment of a monarchy. The first historic dynasty began about 4800 B. C., and Manetho gives the name of the first king as Mena, the word itself meaning the establisher. The name may have been given to him in recognition of the power and ability he displayed in bringing all these different colonies under the rule of a central government. The exploits of Mena, as recorded by Manetho, throw considerable light on the physical condition and climate of Egypt at this early date, and clearly

<sup>1</sup> The Flood of Deucalion and Pyrrha.

<sup>2</sup> All areas of great deposition tend to be areas of subsidence; hence the highland of El Gisir has in modern geological time been the axis on which the Isthmus has revolved, the south side rising and the north side sinking.

<sup>3</sup> These two races had not yet amalgamated at the beginning of the Fourth Dynasty (4034 B. C.), as in the tombs of this period Prof. Dr. Flinders Petrie noticed that the bodies of those he judged were the subservient race were desiccated in a doubled-up form like the ancient Inca Indians, lying with their heads to the north and their faces to the east, while those he judged were the ruling race were buried full length. The skeletons of these two primitive divergent human types are now being studied at the museum of the Royal College of Surgeons, London, and before long we may hope to have more light thrown on the subject.

<sup>4</sup> "Poun," according to Brugsch, means "east," but according to others it means "red." The name was applied in later times to the southern part of Arabia and the Somali country, and no doubt, as the ancient Egyptian tradition was that their forefathers came in this way to settle in Egypt, Arabia was always referred to in the hieroglyphic text as the Ta-Nuter (the Holy Land). For there is no doubt now that Mena and his followers brought with them a purer worship of the sun than they found among the primitive dark skinned colonies, who, besides the sun, that all of them revered, had each a distinctive totem of its own. At a later period in man's history another race followed in the footsteps of Mena, passed through Arabia and crossed the Red Sea, and after lingering in Egypt for some time ultimately concentrated their government on the northern coast of Syria and at Carthage. They were called Pounians, Phounians, or, as we have it now, Phœnicians.

show that in order to carry out great sanitary measures that are to benefit a whole country the central government must take the thing in hand and employ experts. The cataract at Silsilis had either broken through or had become gradually worn away, thus liberating the large body of water which had been impounded above it, and so diminishing the rainfall in the vicinity. Before this water was liberated a large amount of alluvium was deposited for probably 1,000 to 1,400 years, and it may be mentioned as an interesting fact that these large tracts of land, then left high and dry, now only await the magic touch of irrigation to become highly productive. The cataract (granite) at Assouan was still high (100 feet higher than now), and a branch of the river swept round by the present ancient quarries and reëntered the main channel a little to the north of Assouan, making Assouan an island. The cataract at Semneh was also intact, making Ethiopia an extensive lake district. Many of the other cataracts, however, had given way and were now only rapids. Notwithstanding the emptying of many of these inland lakes, and consequent destruction of vegetation, the rainfall must still have been considerable in those regions that are now rainless. Mena, with his followers, seems to have entered the valley of the Nile by way of Arabia and the Red Sea. His first seat of government was at This or Abydos, situated between Assiout and Luxor. At this time, even as now, Abydos was on the border of an extensive fertile plain that required no great skill for its irrigation. Mena no doubt visited Silsilis, and could see at a glance how much was to be gained even by a partial restoration of the cataract there; but for some reason or other he did not attempt it, although he had no mean engineers in those days, they having already built the Temple of the Sphinx and hewn the Sphinx itself in the native rock at Gizeh (Maspero). No! Mena's exploits were carried out in the northern Egypt of that day. In the region between Heliopolis and the Temple of the Sphinx he saw a battle going on among the watery elements, the sea and the river striving for the mastery. The river was throwing its mud in the teeth of the sea, and wherever there was a sand island there the mud was thrown up and rank vegetation soon appeared. The sea, little by little, had to retire, leaving swampy morasses behind it, where the crocodile and hippopotamus were at home, but making the whole of this region malarious and unhealthy to man. Mena set himself to remedy this state of affairs. He was the grand sanitarian of those early days. He caused a great dike to be raised about 30 miles to the south of Cairo and directed the channel of the river into the center of the valley, as it was then flowing by the foot of the Mokattam range on the east side of the valley. This he followed up by raising other dikes as he required, so as to get the control of the river and drain off the marshes. This was evidently the beginning of reclaiming the delta from being a morass; which would no doubt change the climate considerably and make it much less malarious. On part of this reclaimed land Memphis was built, which continued to be a city of some considerable importance down to mediæval times. While Mena was directing his irrigation schemes he was attacked by a hippopotamus and killed, after a reign of sixty-two years. The presence of the hippopotamus would indicate a warm climate, but not necessarily much different from what we have now, for Dr. Abd-el-Lateef, writing at the beginning of the thirteenth century of our era, has recounted that hippopotami were very common in the Damietta branch of the Nile at that time, and even so late as Mohammed Aly's time<sup>1</sup> (1811 to 1848) a hippopotamus was killed near Mansoura in the delta.

<sup>1</sup> Within my own memory there was a rendezvous of crocodiles at Gebel-Abu-Fadah, about 200 miles to the south of Cairo. I saw a whole family of them in 1867. They have since been exterminated by travelers. And as crocodiles and hippopotami live in the same climate the disappearance of these animals from Lower Egypt has not occurred from any change of climate, but from the presence of hostile man. The same may be said with respect to the lion, which used to be hunted by the Pharaohs in the vicinity of the pyramids of Gizeh, and by the Emperor Hadrian near Alexandria. This animal has now retired to the Soudan and equatorial regions.

No doubt the good example set by King Mena was followed by his successors, so that the river was guided in its course and land was reclaimed whenever possible. By the time of the fourth dynasty (4034 B. C.) Bubastis, near Zagazig, was founded and inhabited. The vast proportion of the present delta, however, was still a gulf of the sea, with the muddy Nile running into it and gradually forming the delta. By the sixth dynasty (3500 B. C.) some of the sand islands in the gulf had become inhabitable through the pioneers reclaiming the morass around them. On one of these islands Tanis or Zoan was founded, which played an important part in the history of Egypt in later dynasties. When we reach the twelfth dynasty (2500 B. C.), Amenemhat III, the sixth king of that dynasty, took great interest in reclaiming the swamps and in the proper watering of the land already reclaimed. He is celebrated for having conferred great benefits on his country by the construction of dikes and reservoirs for controlling the water supply.<sup>1</sup> He caused a nilometer to be chiseled on the rocks at Semneh, a few miles south of Wady Halfa, and in connection with it a series of hieroglyphic inscriptions, recording the rise of the Nile during his reign; from which we learn that the waters of the inundation rose on one occasion 27 feet, and on an average  $11\frac{1}{2}$  feet, above the greatest rise of the Nile at the present day. At that time, therefore, the cataract at Semneh had not yet broken down, and Ethiopia must therefore have been a well-watered country. The rock inscriptions also show that the Nile below Semneh rose some 10 feet above the highest Nile of our day, proving that the cataract at Assouan was only being slowly rubbed down; the island of Philæ being of course then under water.<sup>2</sup> The climate of Upper Egypt would still be somewhat rainy, although by this time the Sahara inland sea would be very much contracted from what it used to be. The great dam at Silsilis had broken through its barrier in prehistoric time and apparently no attempt had been made to restore it, unless perhaps on paper, as has been done in more modern times. This Pharaoh (viz, Amenemhat III) has rendered himself immortal by having created an inland fresh-water sea in a natural depression in the Libyan desert not far from the Nile and quite near Memphis. Suffice it to say here that water was conveyed to it from the Nile by means of a canal (the Bahr Yousif of our day), and when the basin was filled it was said to be 450 miles in circumference and at parts 350 feet deep. It was called by the Greeks Lake Mœris,<sup>3</sup> but in the hieroglyphic language it was called Ta-She—the lake country. It continued to act as a reservoir for the Nile surplus of water, and to irrigate the country around till the Roman period, when the dikes were neglected, the sluices fell out of repair, and the water thus ran to waste; so that in the time of Pliny (70 A. D.) it was already dry, with the exception of what still remains under the name of Birket-el-Qoroon, or Lake of the Horns, so named from the form of the lake being like the shape of a pair of horns.

<sup>1</sup> It may be incidentally mentioned here, although it has no direct bearing on the climate of Egypt, that under this Pharaoh the embalming of bodies (which in itself is a great sanitary measure) was more carefully done, as is proved by an examination of the mummies, from this period downward; and besides, the sacredness of the Nile was more insisted on, so that the Egyptians of those days had a purer water supply than the Egyptians of to-day.

<sup>2</sup> It was in connection with the twelfth dynasty that Prof. Flinders Petrie found in Upper Egypt traces of an Ionian colony of workmen that had been employed by one of the Usertesens. At a very early date there were direct commercial relations between Egypt and India, and indirect through Mesopotamia, so that Egypt was often exposed, then as now, to the importation of Indian and Mesopotamian communicable diseases; and notwithstanding the extraordinary attention given to sanitary science by the ancient Egyptians we find from history that every now and again fatal plagues among men and beasts that were not indigenous to the soil devastated the country, showing that the climate was favorable to the propagation of such diseases, and that the country itself was not more sanitary than it ought to have been.

<sup>3</sup> The Greeks, who never acquired any intelligent knowledge of the ancient Egyptian language, would often hear the natives call this lake "Meri," which simply means "lake," and they evidently concluded that it was the name of the Pharaoh who had created it, hence the erroneous appellation—Lake Mœris—has been handed down through the Greek historians.

Very naturally this depression in the desert, after having been constantly filled with the muddy Nile water and partially emptied for irrigation purposes year after year for a period of nearly 2,400 years is, now that it is dry, one of the richest provinces of Egypt. Its present name, "Faïoum," is simply the Coptic name "phiom" or "the sea," carrying us back to the time when, instead of the 231,283 acres of rich arable and cultivated land of to-day, this was a veritable sea. This large body of water must have modified considerably the climatic conditions in its neighborhood; for we must not forget that where we have fresh water to deal with in a warm climate we have always an abundance of trees<sup>1</sup> and vegetation that materially and sensibly affect the temperature and rainfall. The Faïoum now is a malarious district, but more especially in the vicinity of Lake Qoroon,<sup>2</sup> which is brackish; and the rainfall is almost *nil* throughout the whole of this region. Amenemhat III died about 2266 B. C., and was succeeded by a number of kings of little account as far as this paper is concerned. Still, about 2200 B. C., the fourth Pharaoh of the thirteenth dynasty made a record on the nilometer at Semneh, showing that the cataract there was still holding out; yet, under the sixth Pharaoh of this dynasty, monuments were erected on the island of Argo considerably to the south of Semneh, but below the level of the formerly dammed backwaters of the cataract. Some time, therefore, between these two reigns, a period of only sixty-six years, the Semneh Cataract must have rather suddenly given way and caused a destructive flood from all along the course of the Nile to the sea, and famine<sup>3</sup> would have been the natural result of such a sudden catastrophe. Ethiopia was now left high and dry, and became more or less a barren waste, even as it is to-day. It is with great labor that the natives now raise the water from the Nile to irrigate their little patches of ground, simply to grow sufficient to keep them alive, and I fear that famine is not uncommon among them. Here, then, another rainless district has been produced and it remains so. We may now say that the whole stretch of country from Assiout to Berber, which had an abundant rainfall in ancient times, is now almost without rain. No doubt this would be reversed if the cataracts were restored, a new Lake Mœris created at the border of the ancient one, the Sahara<sup>4</sup> refilled with sea water, and the Eurasian Sea restored, for under these circumstances the rainfall would again be excessive. As far as the restoration of the cataract and Lake Mœris is concerned, this has been studied by the Egyptian Government<sup>5</sup> for several years past, and the study is still being pushed forward by American,<sup>6</sup> French,<sup>7</sup> and English<sup>8</sup> engineers. When we go up the Nile as far as Berber,  $17\frac{1}{2}^{\circ}$  north latitude, we enter the region of the tropical rains that, following the course of the sun, and falling in torrents

<sup>1</sup> The ancient Egyptians were much more fond of arboriculture than the modern Egyptians. The sculptures tell us that Ramses III, twentieth dynasty, about 1280 B. C., "over the whole land of Egypt planted trees and shrubs to give the inhabitants rest under their cool shade."

<sup>2</sup> Lake Qoroon is now about 35 miles long and 7 miles broad, and is on an average 28 feet deep. It rises and falls with the Nile, although it is always many feet below the level of the Mediterranean.

<sup>3</sup> A very interesting hieroglyphic inscription on one of the rocks near Assouan records a famine of seven years under an early Pharaoh. Another 7-year famine is recorded as having commenced in 1064 A. D.

<sup>4</sup> M. de Lesseps projected a scheme for letting the Mediterranean into the Sahara depression, by cutting a wide canal to the south of Tunis, commencing in the Gulf of Gabes.

<sup>5</sup> *Vide 4.*

<sup>6</sup> W. Cope Whitehouse, an American engineer, has for years been very enthusiastic over a new Lake Mœris nest or depression he thinks he has discovered in the Faïoum district, which would act admirably as a reservoir for the surplus water at high Nile and be a source of water supply at low Nile.

<sup>7</sup> M. de la Motte, a French physician, has been for years advocating the restoration of the Silsilis Cataract.

<sup>8</sup> The English engineers of the Egyptian Government have proposed to construct a dam at the first cataract, but to the south of the island of Philæ, so as to save that island from submergence.

on the Abyssinian mountains, and in the equatorial regions, create the Blue and White Nile, which, uniting at Khartoum, form the river that makes Egypt a habitable country. These rains are periodical and produce the annual rise of the Nile, to which we in Egypt are so accustomed that we often forget that a few feet above the annual rise or a few feet below the average fall means famine and disease. The usual difference between high and low Nile may be taken as 40 feet at Assouan, 25 feet at Cairo, and only 4 feet at Eamietta and Rosetta; but in ancient times, with a greater rainfall and a fuller river, these figures would have to be nearly doubled. We have seen that reclaiming the delta was a very gradual process; and even at the present time the Government is draining the swamps and lakes to make the districts around them more healthy, as well as to have the land available for cultivation; and such reclamation must proceed so long as the Nile continues to bring down such large deposits of alluvium from Abyssinia and Central Africa. Formerly the delta swamps formed an inaccessible hiding place for culprits, refugee kings, and their followers; and they were also the home of the plague, pestilence, and other serious forms of disease recorded in history, or at least favored their propagation when imported. The rainfall in the delta for 30 miles inland is now as much as 10 to 12 inches annually, influenced in some measure, no doubt, by the large salt marshes and lakes lying across the 160 miles of Mediterranean front, viz, Mareotis, near Alexandria, covering 250,000 acres; Edko, 100,000 acres; Burlos, 300,000 acres; Aboukir, 50,000 acres; Menzaleh, 500,000 acres, and Sirbonis, near Palestine, 100,000 acres. Most of the lakes did not exist in comparatively ancient times, but the districts now covered by them were richly cultivated and supported a numerous population.

Lake Menzaleh was formerly a district celebrated for its fertility, but in 535 A. D. the sea broke through and submerged the eastern portion, and by 540 A. D. the whole of this region was totally under water. All the towns on the low levels were destroyed by submergence and only those that were built on high ground escaped, but they became so malarious and unhealthy that after a time they were deserted and even the country around that was not submerged became swampy, unhealthy, and ruined for agricultural purposes, just as it is to-day, so that the population in this region has always remained scanty.

The present Lake Mareotis was originally a small sweet-water lake surrounded by a famous vine-growing district, celebrated in ancient times for its fertility and salubrity; but in 1801 A. D. the sea was intentionally let in for military purposes, and this entirely destroyed the whole district and converted it into a malarious environment of Alexandria, which otherwise would be a much healthier city than it has been ever since this regrettable event. About the beginning of the Christian era Lake Sirbonis was 125 miles in circumference, and more anciently was much larger, and is said to have engulfed a whole wing of the army of Ochus, King of Persia. It is now an insignificant lake, having little or no perceptible effect on the climate in its neighborhood.

Lake Abookeer has recently been drained and is now being cultivated. This will do away with the malarious swamps in its vicinity and render this part of the country once more healthy.

I can not close this paper without saying something about the influence of the condition of the Isthmus of Suez on the climate of Lower Egypt. In even late geological time we have seen that Africa was an island, so that the Isthmus of Suez is of recent formation. While "the tongue" of the Red Sea still came as far north as El Gizr, it increased the rainfall in Lower Egypt and modified the climate in its vicinity considerably. When it dried up, naturally the rainfall depending on it ceased. This is proved by the fact that since the refilling of the Bitter Lakes and opening of the Suez Maritime Canal, in 1869, we are having a

greater rainfall again in Lower Egypt, aided, no doubt, by a more extensive irrigation and planting of trees, which the Government is wisely encouraging. This, however, brings me to speak of the climate of modern Egypt, which I have discussed elsewhere.<sup>1</sup>

## THE CARE OF THE PUBLIC HEALTH A NATIONAL DUTY.

A NATIONAL BUREAU OF HEALTH.

By P. B. ARMSTRONG.

The United States Government everywhere typifies all that is good and thoughtful for the welfare of the masses. Yet, strange to say, it has made little or no determined effort looking to the preservation of the public health, the protection of its citizens from the ravages of disease, or the prolongation of the lives of its people. Good health is so universally sought, is such an absolute necessity to material and financial success, that its possession should be labored for before everything else. There is no man who has accumulated wealth and lost health who would not gladly exchange the former for the latter. In 1879 a National Board of Health was established, and for a time was quite active. In 1882 Congress stopped appropriations for its support, and it vanished. It is believed that the abandonment of such a wise project was due to the influence of men who held executive positions in State quarantine or other public health bodies. We suggest the establishment of a national bureau of health on the broadest basis, and conducted, under the control of the Government, by expert sanitarians, believing that it would accomplish more during the first fifteen years of its existence toward the suppression or the modification of disease than has been accomplished in the whole history of man. We realize that its establishment would constitute a vast undertaking, and to perfect it would not be the work of a day or a year. What we seek is to absolutely banish all contagious and infectious diseases, and until that can be done to modify their virulency.

The diseases which carry off the vast majority of the human race are those which can be very greatly restricted in severity and volume or completely exterminated. Among the deadly list are tuberculosis, pneumonia, diphtheria, smallpox, measles, scarlet fever and typhus fever, cholera, and yellow fever. If these most virulent forms of disease can be controlled is it not reasonable to assume that all diseases of a contagious or infectious character can be? An eminent physician says: "They may be largely limited, or almost wholly blotted out, by intelligence and care." Antidotes have been found for every class of poison, and specific remedies are now administered for quite every form of disease. This leads us to believe that by a concert of action on the part of the National Government with the great life insurance companies methods for prevention or for the modification of the severity thereof can be provided for all contagious and infectious diseases which will prove as effectual as inoculation for smallpox and hydrophobia. Upon page 12 of the Transactions of the Seventh International Congress of Hygiene and Demography, held at London (England) August 10 to 17, 1891, we find the following brief inquiry made by one of its learned members: "Why, if diseases are preventable, are they not prevented?" The answer to this was:

That while an instructed minority may understand the importance of observing hygienic laws, a very large section of the community is careless of and indifferent to their observance, and consequently the portions of those laws which are individual and personal in their application are left a dead letter. Acts of Parliament are of little avail so long as the people they are framed to guide do not real-

<sup>1</sup> At the Medico-Climatological Congress, Chicago, in connection with the auxiliary congresses of the World's Fair.

ize their value or importance, and it is quite certain that the only way to stamp out preventable disease is to educate every member of the community to feel the importance of the laws of health.

The discovery of the principle of inoculation as evolved by Jenner and Pasteur, the many discoveries in remedial agents, and the use of antiseptics in surgery show not only what has been already accomplished for the prolongation of human life, but what is likely to be accomplished in every branch of medical and surgical science in the future. We learn, very recently, that Dr. Haffkine has inoculated over 200 persons at Simla, India, for cholera, including many medical men, high officials and ladies. Several native Indian States have taken up his system of inoculation, and it is used at Agra, Delphi, and Lucknow. In one British regiment over 400 men have been inoculated. How successful this experiment may prove is yet matter for conjecture, but it is in line with the theory which we advance as to the eventual discovery of means for the prevention of all forms of disease.

Sanitary science as a humane study is of comparatively recent date. In the history of medicine it has been a question of treatment of disease rather than its prevention. Improved surroundings, a thorough education in sanitary matters, and training of the public mind will be necessary before our people will accept and adopt the required measures in full. Even in England, where within the last thirty years not only the medical profession, but the laity, clergy, and business men, have given some attention to the matter, the work is but in progress, and sanitary arrangements are still far from satisfactory. In the United States, where, by virtue of our form of government, each village, town, city and State, exercises a much greater degree of self-government, that unity of action necessary to the maintaining of the public health can hardly be expected without a thorough education of its citizens. Strange as it may appear, and greatly to their honor, it can truthfully be stated that about the only practical work, from a sanitary standpoint, accomplished in the United States has been by physicians, the stability of whose profession depends upon the occurrence of disease. The great life insurance companies of this country, which have to-day nearly \$12,000,000,000 of insurance in force, covering over 10,000,000 of lives, certainly have a primary interest in the prolongation of human life, and yet they have done absolutely nothing toward encouraging this great reform.

Dr. MacDonald, of Canada; Dr. T. Mitchell Prudden, of New York, and others have written of the possibility of controlling disease, but so far as we have been able to ascertain, the only materialized plan for its accomplishment has been recently suggested through the New York Academy of Medicine and is embodied in a draft of a proposed bill to establish a bureau of public health, which it intends to submit to the next session of Congress. Their proposition as now before us contains one vital defect; it would make the bureau an adjunct of and subservient to the Treasury Department, instead of a department standing as clearly alone as the Treasury Department itself. Unless stringent measures are used in establishing this bureau, it will become a part of the political machine of the party in power, thus destroying in a large measure its usefulness. The proposition of the Academy of Medicine requires the members of the bureau to attend to this duty only upon occasion, and pay them a *per diem*. This would not attain the end in view. How much more rapid would be the advance of science in suppressing or preventing disease should such bureau devote its whole time, knowledge, and influence to that one subject? The question of saving a few dollars should not enter into so important an undertaking. The object should be to prevent disease and to prolong life, regardless of cost. The first steps taken by the National Government should be the passage of stringent laws regulating the health of immigrants, the sanitary condition of goods imported, and the sanitary condition of

every city, town, and village throughout the country. Do away with noxious surroundings, polluted atmosphere, and impure water; prohibit the sale of articles of food deleterious to public health, and a great and important preliminary work will have been accomplished. What can be accomplished toward the prevention of disease will be better understood when it is known what has been done with one disease in one State. A conservative comparison and estimate shows that in the State of Michigan alone, during the three years, 1886-'88, at least 10,000 cases of diphtheria were probably prevented and more than 1,700 lives saved by intelligent isolation and disinfection. If that was accomplished in one State in three years, with but local industry and power, think what might be done in the entire Union if the mighty arm of the Government, controlled by the highest medical and scientific skill, was directed toward the extirpation of disease.

The medical associations of the United States at the present time have no power to compel the adoption of valuable sanitary suggestions, as their recommendations are viewed with jealousy and are uniformly regarded as gratuitous by the health authorities, whose appointments are habitually made on the ground of political service or political preferment. Such bodies as are now working in the interests of the public health should become a part of the proposed organization, as also the Surgeons-General of the Army, Navy, and Marine-Hospital Service. By the establishment of such a bureau sanitary science would be advanced by the practical application of sanitary laws, by educating and preparing sanitary men throughout the entire country, and by the appointment of scientific men instead of, as now, men of no particular training in their specialty.

Our proposition for the remedy of this evil is substantially as follows: That the sanitary service throughout this country be divided into local, State, and national; that an arbitrary supervision over each department be exercised by the Federal Government; that all appointments shall be free from political vicissitudes; that the management of each branch shall be in the hands of paid officers, who shall gather and classify statistics and present measures to Congress in the interests of public health; that such officers shall be in correspondence with representatives of boards of health in every State in the Union; that the residence of the sanitary representatives shall be in the State of which each is a legal resident; that one or more laboratories shall be established in each State for the analysis of all material concerned in the production and propagation of disease, and for the discovery of the conditions favorable to its growth, and that the internal and coast quarantine shall be under the control of the national bureau. We further suggest that the education and care of children and an examination of the condition of children in schools, workshops, and elsewhere be carried out upon a fixed plan—a comprehensive and systematic inquiry into the causes of diphtheria, children's diseases, such as scarlet fever, whooping cough, etc.; the habits of children in school, and their cramped position at desk; their time and methods of open-air exercise during school hours; a careful and systematic inspection of all public and private schools; the instruction of girls and women in domestic hygiene as part of their education; special regulation for the control of block dwellings for the industrial classes; special examination and registration of architects; instruction, examination, and registration of plumbers; the cremation of such as die from infectious diseases; the compiling of statistics as regards sick insurance—the results to be classified as to sex, age, conjugal relationships, and occupation; the actual occupation, how long engaged in same, hours of work, previous occupation, and duration of illness; in diseases that terminate fatally, the predisposing cause, the duration of illness, and the cause of death, all with a view of destroying, if possible, the causes of sickness or delays in restoration to health. The difficulties in effecting such organization will be; first, from the opposition of those now in power, who, under the new organization, may be replaced in course of time by trained sanitarians; and

second, from the prejudice which exists in some States against the centralization of sanitary power. Let the public, however, become educated to the fact that all contagious diseases can be kept out of our cities and homes by the rigid observance of simple sanitary laws, as cholera has been kept out of New York for the past two years by quarantine, and any official who opposes the progress of a bureau of public sanitation will be immediately swept out of official life. No political party or politician dare suggest, at the present day, the withdrawal of the protection of quarantine or the abandonment of hospitals for the isolation of contagious diseases. Let the public once appreciate that these are but a few steps that the general or local government have taken toward the improvement of the health and physical condition of its citizens, and the demand will go up from all parts of the land that the General Government go forward in the line of its duty. Who are the proper parties to educate the public as to the duties of the Government, and their rights in this important matter? We believe a combined movement on the part of the great life insurance companies, assessment associations, and fraternal organizations, representing over 10,000,000 policy holders, headed by the officers of these companies and associations, could bring to bear upon Congress a power that would result in the prompt establishment of a national bureau of health, and thereby benefit mankind, prolong life, and give to our citizens the blessing of health which is above and beyond all other gifts or benefits that it is within the power of Government to confer upon its citizens.

---

#### MUNICIPAL SANITATION IN ST. LOUIS.

By GEORGE HOMAN, M. D., Health Commissioner.

The practical application of the principles of sanitation in a new or comparatively new country is, from the conditions presented, largely experimental, and therefore lacks the precision and completeness which may be seen in older communities having more settled characteristics and where the necessity for thoroughness in this respect is more fully recognized and understood. And this aspect of the question must of course be considered in rightly judging whether a given community has or has not lived up to its responsibilities in respect of sanitary work. In St. Louis the progress of municipal hygiene has been hampered in divers ways, and the full realization of the possibilities of preventive sanitation in the field there presented delayed through various adverse causes. The naturally good facilities for surface drainage existing there have exercised a beneficial influence on local health, and this advantage has been reënforced by artificial means to no small degree, so that the removal of rainfall, and the delivery by sewerage of the liquid waste of a large portion of the city into the Mississippi River goes on rapidly and efficiently. The public drainage system is placed in charge of a special branch of the city government, termed the sewer department, and the same is true of the public water service, and also the cleaning and maintenance of public streets and alleys; so that it is only secondarily that the health department figures in connection with questions having a sanitary bearing coming under the immediate jurisdiction of these several departments. Rapid growth in population and expansion of closely peopled territory beyond present attainable sewerage bounds have raised many difficult questions and offer knotty problems demanding prompt solution aside from the mere matter of drainage, although that of course is always one of prime sanitary interest and importance.

The plan upon which the health department of St. Louis was projected and created has many good features, and others not so good. Upon assuming charge of it about the end of last May I presented to the board of health, as the advisory

power therein, a plan of reorganization for sanitary work, the main features of which plan will presently appear. The sanitary division of the health department has immediate charge of the city's health, and is the direct agency by means of which complaints are investigated, inspections made, nuisances abated, offenders against sanitary law brought into court, etc. For the effective performance of this service the distribution of the work must be arranged for with reference to systematic coöperation by the entire force concerned in its accomplishment. In order to meet the foregoing requirement the force available for sanitary work was assigned as follows: (1) A corps of intelligent, active men was detailed for the duty of making sanitary inspections and house-to-house visitations, this force being divided into squads, each in charge of an experienced man and held responsible for the good condition of certain prescribed districts. (2) A corps of ditchers and drain layers for the abatement of pond nuisances on public property and other work of like kind. An important part of the work performed by this force is the laying of sanitary house drains in suburban localities that are beyond the reach of the regular system of sewers. (3) A house-posting and disinfecting corps for the work of public notification and suppression of communicable diseases. This branch of the division contains a number of physicians who come in contact with those members of the medical profession reporting cases of such diseases. The others attached to this force do the routine disinfection work. It is in present contemplation to reorganize this corps, uniting with it the public vaccination service, and constitute it a separate division under expert medical direction, equipped with all the latest approved means of attacking infection lodged in human habitations, fomites, etc. (4) A corps of men for the disinfection of public alleys, rear yards, and other offensive conditions by means of chemical solutions applied by sprinkling carts or other suitable means. This to be a temporary service only, intended for use in hot weather when putrefaction goes on most rapidly, and to be applied in closely built and thickly populated districts. (5) A corps of men for the inspection of meat, fish, poultry, and game in meat shops and butcher stalls, and the condemnation and seizure of all market supplies of this kind found to be of bad quality. Besides this duty they inspect slaughter-houses, yards, and pens where butchers' stock is kept, sausage factories, etc., coöperating with the men of the corps first mentioned, and doing such other work as may be assigned them. (6) A small corps of men appointed under the law authorizing the reduction of garbage by the Merz process, a company organized for that purpose having a ten-years contract with the city for the disposal of all garbage and dead animals delivered to them. The collection and removal from the streets and alleys of slops and garbage to be thus reduced is done under a separate contract with the health department, the latter, together with the police department, being charged with the duty of seeing that the terms of the contract for garbage removal are enforced. (7) The office of city chemist was revived with provision for competent assistance and ample laboratory facilities, and this addition to the working force of the department has proved of great value. While by law this branch of the department is placed directly under the supervision of the board of health, and not the health commissioner, still the sanitary division receives great assistance from it in its work, inasmuch as a part of the duty of the city chemist is to make analyses of all suspected food substances, water supplies, ice, etc., and as the number of surface wells in St. Louis is large, the condemnation of which must be preceded by chemical test, an extensive field for work is opened in this direction.

Another important service confided by me to this office is the work of photographing the various establishments and conditions complained of as nuisances, the parties responsible for which are summoned in due course before the board of health for a hearing on the question of condemnation. These concerns are of

various character, comprising bone-boiling and bone-drying places, fertilizer works, rendering establishments, candle factories, dairies, slaughter-houses, and many other kinds. In some of them large property interests are involved and, in addition to the oral testimony given at the hearing, the evidence afforded by the camera is a very valuable aid in obtaining a clear understanding of the situation and in reaching a just conclusion in the matter. And, further, when it is found necessary to carry cases into court the photographic evidence is still useful. This agency has been adopted as a permanent feature of sanitary work, and its application and development in this line has thus far abundantly proved its value. The health department has an auxiliary in the office of the dairy and milk inspector, the officials of which, however, are not subject to direction by the department, but coöperate in its work upon request.

The projected plan of work as herein outlined has been in successful operation all summer with the exception of the fourth corps, lack of time and money for its proper organization having prevented its being placed in the field. At the outset of the sanitary campaign thus undertaken the proper points of attack were ascertained by a pin-and-map method; that is, the records of the department showing reports received of dangerous diseases were consulted, reaching back for a year or more, and the location of all such cases were indicated on a city map by means of pins. Of course wherever the pins clustered most thickly a local disease center was indicated, where sanitary work was most urgently needed; and this method has been found to serve other department ends in a very effective way. The sanitary division in its preventive work is necessarily in close relation with that other division to which is assigned the duty of treating the indigent sick in their homes, securing their isolation, if need be, and, if necessary, removing them to hospital. In this work, when cases of communicable diseases are to be handled, the manner in which it can be done with a minimum amount of danger to the public has to be considered; also the speed of its accomplishment, consistent with the comfort and safety of the patient. To meet these requirements, and in view of the especially favorable conditions presented therefor in St. Louis, a system of electric railway ambulances has been projected and is now in course of accomplishment whereby the delivery of sick and injured persons, the dependent insane, and the indigent coming under the municipal charge may all be transported to their appropriate destination with a far greater degree of speed and comfort, and of safety both to themselves and the public, than by the horse ambulances which they will replace.

An important municipal step in the direction of increased public comfort and health was effected some years ago, when a general system of streetsprinkling was begun, the cost of which is assessed against the abutting property; and this, following the general replacement by granite, asphalt, and wood-block pavements of the soft, broken limestone previously used as paving material, has most markedly abated the dust nuisance formerly so grievous when this work was done piecemeal and the street surface was easily pulverized.

There is no reason to doubt that a decided decrease in the number of cases of respiratory affections due to atmospheric causes, and alleviation of such troubles, has followed these two innovations. The city atmosphere is still impure in that it ordinarily contains palpable matter in suspension; this manifest impurity consisting of soot and smoke due to the imperfect combustion of the soft coal almost universally used. But energetic measures are now being taken to remove this drawback through the compulsory use of smoke-prevention devices, with very good prospect of ultimate success, and thus bring relief from that which is an evil in a cosmetic as well as sanitary sense. In close connection with the consideration of the purity of air must be ranged the question of the freedom of the public water supply from contamination by suspended or dissolved impurities; and the unsightly appearance of St. Louis water as commonly presented, due to admixture of mud and clay,

has tended no little to her discredit, even though the organic taint found in it be inconsiderable. But this reproach is also in course of removal through the construction and near completion of new pumping works and settling basins 7 miles above the present intake, the tax on the capacity of the present works being so constantly great as to not afford time for the sedimentation of the daily supply. The chief avenues by which disease may enter the human body are three in number; namely, the respiratory tract, the alimentary tract, and the cutaneous surface; and if the vehicles carrying the organisms of disease are searched and sterilized before entrance is gained the development of forms of communicable diseases within the body may not occur. This, of course, requires that the air shall be free from mechanical irritants and living pathogenic germs, so that no morbid process may be set up in the air passages and that ingested food and drink shall not contain the elements of bacterial infection. It also implies that no foe to health and life be introduced by cutaneous or mucous inoculation, for with all these portals securely guarded the citadel of the body is quite safe against attack. To assure this immunity to every inhabitant is the aim of all municipal sanitation, and St. Louis has made provision, it may be in all respects not fully systematized and complete as yet, to bring this within reach of her people, and with fair assurance of success.

The school of experience is sometimes the only one in which either cities or individuals can learn, and the price of tuition is often high, but the lessons thus learned are usually not forgotten. St. Louis has not been exempt from instructive lessons of this kind, and has profited wisely in the main by her mistakes, so that it may be said now that the cause of public health rests on a sure foundation and that progress is steady in the right direction. And while, perhaps, it may not be claimed that on her site the ideal city of health will rear its halls and towers, still her people, through vigilant, wise sanitation and advancing knowledge, will assuredly enjoy a freedom from all forms of preventable diseases equal to any, and superior to very many, of her sister municipalities of near or equal size.

---

## CAUSAS Y MODO DE PROPAGACIÓN DE LA NEUMONÍA LOBAR AGUDA.

Por el Doctor DOMINGO AVAÑAMO, México.

La neumonía es la enfermedad que produce mayor mortalidad en la República Mexicana, después de las fiebres, pues pasa de la cifra de 100 por mil defunciones en varias localidades de la Mesa Central. La enfermedad ataca mayor número de distritos en la parte de la República comprendida entre los 17° y 24° de latitud. Invade particularmente la parte alta del país ó tierra fría, notándose sin embargo, que se presenta en muchos distritos de la tierra templada y en algunos de la tierra caliente, en particular en la costa del Golfo. La zona más invadida comienza en el norte de los Estados de San Luis y Zacatecas; sigue por todo el Estado de Jalisco y la parte occidental de Michoacán, en donde disminuye algo en el distrito de Tacámbaro; continúa en toda la parte oriental de todo el Estado de Michoacán, todo el Estado de Querétaro, exceptuando el distrito de San Pedro Tolimán, y sigue después exceptuando muy pocos distritos por todos los Estados de México, Hidalgo, Tlaxcala, Distrito Federal, la mayor parte del Estado de Morelos y casi toda la parte norte del Estado de Guerrero. Fuera de esta zona de mayor invasión hay otras varias pequeñas, diseminadas en toda la República, haciéndose notar muy particularmente la que ocupa toda la parte oriental del Estado de Campeche y una pequeña del de Yucatán.

Se puede decir de una manera general, que el número de casos de neumonía que se observa en las poblaciones está en razón directa de la altura; así es que las ciudades de Zacatecas y Toluca, de los Estados de Zacatecas y de México, respectivamente, y la pequeña población del Guarda en el de Morelos, cuyas poblaciones son de las más elevadas de la República, son aquellas también en que son más numerosos los casos de esa enfermedad.

El fin del invierno y principio de la primavera, es la época del año en que se observa más frecuentemente y con el carácter más grave. Las principales condiciones meteorológicas que nos han parecido coincidir con la exacerbación de la enfermedad, son la disminución de la presión atmosférica y de la humedad del aire, el aumento en la velocidad del viento y la mayor extensión de las oscilaciones diurnas de la temperatura.

Durante los meses de marzo y abril es común observar en varias poblaciones que algunos puntos son invadidos con mayor intensidad. Respecto de la ciudad de México, se ha notado que en aquellas habitaciones expuestas hacia el norte y en todas aquellas que se hallan á lo largo del canal de la Viga, que es el que conduce principalmente los desechos de la ciudad, es donde el número de casos es más frecuente. Por lo común hay varios casos á la vez, sucesivamente en cada habitación, y se ha notado varias veces por muchos médicos que ejercen en la ciudad, que las personas que están en contacto más inmediato con los enfermos son también las que con más frecuencia sufren después la invasión de la enfermedad. Pudiera citar muchos hechos recientes que confirman el contagio de la neumonía, pero esto alargaría demasiado este escrito, y por lo tanto solamente indicaré lo siguiente: Primero, que es común observar que varios individuos que habitan la misma casa sean atacados sucesivamente con diferencia de pocos días; segundo, que se han notado otras, que un individuo de fuera de la población que va á visitar á alguno de sus parientes atacado de neumonía, no es raro que contraiga la enfermedad y que regresando después á su población transmita la enfermedad á las personas que habitan con él; tercero, que se ha observado algunas veces en los hospitales la presencia de numerosos casos de la enfermedad y esto de ordinario en la misma sala y no raras veces en enfermos que estaban más cercanos uno á otro; cuarto, que también se ha observado la invasión simultánea de la enfermedad en varios miembros que habitan la misma casa.

Todos estos hechos agregados á los que se han observado ya en otros países no hacen sino confirmar la creencia, casi general ahora, de la contagiosidad de la neumonía. Pero al mismo tiempo que confirman esta creencia nos indican la manera como la transmisión se verifica. Indican que lo mismo que el tifo, la neumonía se transmite por el contacto directo del enfermo ó de sus ropas y también por el aire, aunque á distancias muy cortas, de pocos metros. Otra clase de hechos se han observado también en la ciudad de México que parecen demostrar que los gérmenes que produce la enfermedad se conservan y propagan en las atargeas y albañales. Además del hecho señalado al principio de que la enfermedad es más común á la orilla del canal de la Viga, hay este otro hecho de observación, que al ir descubriendo las atargeas en diversas calles de la ciudad, con el objeto de hacerla limpia de ellas, lo que se verifica todavía, por desgracia, de una manera enteramente primitiva é inconveniente á pesar de las advertencias del consejo de sanidad, se va observando que la neumonía se desarrolla en algunas calles del trayecto, al mismo tiempo que el tifo y algunas fiebres de forma intermitente.

En otros países se han observado hechos semejantes. Bautí atribuyó una epidemia de pulmonía que hubo en Florencia hace pocos años á los efluvios que se desprendían de los detritus del Arno, que se había desecado y á donde van á dar los desechos de los albañales de la ciudad. De la misma manera en Dublin, Grinshau y More han notado varias veces que la neumonía se desarrolla en aquellos indivi-

duos cuyos alojamientos se hallan invadidos por las emanaciones de los albañales. El año 1882 en París se desarrolló una epidemia de pulmonía en el hospital de la Salpêtrière después de la limpia y reparaciones que se hicieron en los albañales. Pero una de las epidemias que comprueba á nuestro juicio de una manera más evidente la influencia nociva de los gases de los albañales, es la que tuvo lugar en la pequeña ciudad de East Sheen el año 1874. En frente de la ventana de una escuela había una boca de albañal; la municipalidad mandó colocar un obturador, dispuesto de tal manera que se pudiese ventilar el albañal del exterior al interior, pero no al contrario; algunos días después, habiendo aumentado súbita y considerablemente la presión del aire del albañal después de una fuerte marea, se produjo una corriente en sentido inverso, saliendo los gases al exterior y proyectándose hacia la fachada de la escuela. En la tarde de ese día los criados del establecimiento, que tenían sus cuartos en el frente del edificio, no podían soportar el mal olor y al día siguiente uno de ellos fué atacado de pulmonía, después otros dos, y por último dos alumnos; todos estos enfermos tenían sus habitaciones con ventana á la calle. Se mandó clausurar la escuela, se tapó la abertura del albañal y ya no volvió á presentarse ningún caso nuevo. El año 1887 recuerdo haber sido llamado para asistir á unos enfermos en el número 9 de la calle de Venero en la ciudad de México; me encontré con cuatro enfermos graves, tres de neumonía y uno de una fiebre perniciosa perfectamente caracterizada que subió á 41° C. La única causa á la que se pudo referir estas enfermedades fué á la limpia de la atargea de la calle, la cual no se había limpiado hacía seis años; se hallaba azolvada, y al quitar las tapas que la cubrían, los gases fétidos contenidos allí inundaron la habitación de que se trata, produciendo una extraordinaria fetidez y originando desde luego dolor de cabeza, desvanecimientos y náuseas en todos los habitantes. Casi al mismo tiempo tuvo lugar la invasión de la enfermedad en los cuatro enfermos de que se ha hablado. La translación del de fiebre perniciosa á otro lugar impidió que se repitiera otro acceso, y respecto de los otros tres enfermos de pulmonía, sanaron dos y murió el otro, un niño de ocho meses.

He oído referir á algunos compañeros de la profesión de casos de neumonía y de tifo que han estallado á la vez en una misma habitación y cuya causa no podía ser otra que las emanaciones de los albañales. También he sabido de varios casos de niños en el período de lactancia que han sido invadidos ya de neumonía ó bien de tifo, estando sana la persona que los criaba lo mismo que las demás de la casa, no habiéndose puesto en contacto directo ni indirecto con algún enfermo, y no pudiéndose, por último, encontrar otra causa sino las emanaciones de los albañales. Estos últimos hechos que acabamos de referir demuestran la naturaleza infecciosa de la neumonía, así como los que referimos antes, demuestran su naturaleza contagiosa. Pero á los casos de contagio inmediato que se han citado en gran número desde hace ya tiempo, se han añadido hace poco otros casos de contagio mediato, perfectamente comprobados. La ropa de los enfermos, tanto interiores como de cama, han sido los principales agentes del contagio. Entre varios otros podré citar los dos siguientes, referidos por Flint:<sup>1</sup> Un hombre murió de neumonía el 9 de mayo de 1883; la hermana de este hombre, que vivía en una casa distante dos kilómetros, prestó el día del fallecimiento algunas sábanas y un cobertor de lana á su cuñada; un mes después mandó á traer estos objetos, de los que algunos habían servido para cubrir el cuerpo del difunto. Estas ropas, sin haber sido lavadas, fueron empleadas para el uso de la cama de un niño de cinco años. El 10 de junio este niño, que no había salido de la habitación ya hacía tres semanas, fué atacado de pulmonía. El hijo de un tapicero que llevó á su casa un sillón perteneciente á una persona que estaba en la convalecencia de la pulmonía, fué atacado por la enfermedad tres días después. Por último, una criada cuya

---

<sup>1</sup> La pneumonie lobaire aiguë, par le Dr. M. Boulay : Paris, Tome I.

ama estaba atacada de pulmonía fué á ver á su madre á una ciudad distante y durmió una noche en la casa. La madre de esta criada fué atacada de pulmonía.

Las habitaciones son también un vehículo frecuente de transmisión de la enfermedad; se ha visto, en algunas ocasiones, que cuando ocupa una familia una habitación en la que ha habido un enfermo de neumonía, alguno de sus miembros es invadido poco tiempo después por la misma enfermedad, y por lo común es la persona que ocupa la pieza en donde antes había estado el enfermo de neumonía. Varios autores han citado últimamente el hecho de la frecuencia de las pulmonías en algunas habitaciones. Schroeder<sup>1</sup> ha observado en una sola casa, en que los inquilinos se habían cambiado muchas ocasiones, 31 casos de neumonía de 1868 á 1882. Yo he visto en una habitación de los médicos del hospital de Jesús, de la ciudad de México, que han tenido lugar ocho casos de neumonía durante un período de diez años.

Esto parece demostrar la resistencia de los agentes que producen la enfermedad, á los medios ordinarios que originan la destrucción de la mayor parte de los microbios.

El neumococo, que tiene por vehículo los esputos de los neumónicos, se ha visto que puede resistir á una desecación de estos esputos, verificada hacía cuatro meses. La resistencia para el frío de este microorganismo también es notable, pues no muere, colocándosele en el hielo durante muchos días. La luz solar directa que produce la muerte del bacilo de la tuberculosis en pocos minutos, y la luz difusa que tiene el mismo efecto después de algunas horas, no produce el mismo resultado en el neumococo, sino después de un tiempo mucho mayor.

No sé que se haga uso todavía de las prácticas de la desinfección en ningún país tratándose de la neumonía. Por lo que toca á México no sé que hasta ahora se haya pensado en recurrir á dichos medios, pero el número de casos tan considerable de neumonía que se observa todos los años y la reflexión acerca de los hechos que he mencionado y de otros muchos que se pudieran citar, es seguro que han de obligar muy pronto á las autoridades sanitarias á colocar la neumonía entre las enfermedades que exigen las providencias dictadas para las otras afecciones simóticas.

## THE NEED OF RESEARCH IN PREVENTIVE MEDICINE.

By JAMES M. POSTTE, M. D., of Hinkley, Ala.

During the hours passed in meditation upon a subject for the Pan-American Medical Congress there was none which came so vividly to mind as the need of research in preventive medicine. We realize the pressing need of the subject in hand when we see our country threatened by the various epidemic diseases which come to our shores from foreign lands. Also the appeals of our people to the quarantine officials and board of health to stamp out any and all contagious diseases which rise within our borders. In the perspective of the past we see the clouds of superstition and ignorance gently rolling backward and giving way to the brilliant sunshine of advancing knowledge. We are nearing the point, and rapidly, where the old saying, "An ounce of prevention is worth a pound of cure," will be fully understood, even by the laity. It is not many years since the physicians began to inquire more deeply into the etiology of disease, and to the tireless efforts of the scientific investigator we are indebted for our present knowledge of bacteriology. Beginning with comparatively no knowledge upon the subject and with the simplest possible methods at hand they have evolved the present

<sup>1</sup> *Loc. cit.*

system of research, which is of so much importance to us as physicians and surgeons. And when we consider the valuable service rendered by Lister, Virchow, Billroth, Pasteur, and others, we are led to wonder how they have accomplished so much. Sanitary science and hygiene play a most important part in the subject under consideration, and of them it is only necessary to say that a careful perusal of the latest and best works will bring convincing proof.

After thirty years of patient investigation Jenner was able to give us the valuable knowledge that there was one disease which could be ameliorated, and in many cases complete immunity obtained therefrom, by the process of vaccination. If one, why not many? If many, why not the vast majority of diseases with which we are afflicted? With the single proof our conception carries us on until we are lost in contemplation of its possibilities. The identification by Nicolaier of the bacillus of tetanus or lock-jaw, and the absorption of its ptomaines, the elucidation of its preventive treatment by Kitasato, marks a most important point in our history. He has shown that by the introduction of iodoform within an hour or two after the production of a wound it will destroy the baccilli and prevent the formation of their ptomaines and the resulting absorption. Koch, by the recognition of the bacillus tuberculosis and the comma bacillus of cholera, or the spirillum, as we now know it to be, has conferred a lasting benefit upon mankind. As a result of his research we are taught to destroy all tuberculous sputum and to prevent the contamination of healthy individuals with those who have either of the diseases. The chemical discovery of tyrotoxicon and its clinical manifestations by our honored president of this section, Dr. V. C. Vaughn, with the sources of contamination; the discoveries in the etiology of erysipelas, anthrax, and many skin diseases; the valuable contribution of Dr. Roswell Park in regard to the bacillus coli communis, which was read before the American Surgical Association, June 1, 1893, and which is given to us in the last number of the Annals of Surgery; the great impetus given the study of surgical bacteriology by Drs. R. Park, of Buffalo, Nicholas Senn, of Chicago, and many other noted surgeons of the past and present; to those mentioned, and the countless number unnamed, humanity owes a debt of gratitude which it never can repay, and this Pan-American Medical Congress should return to them their sincere love, honor, and veneration.

With this reference to a few of the points which are leading us to the position of preventive medicine, it is not necessary to enumerate further, for the outcome is obvious. And there comes a further thought, combined with a desire to see America represented in the first ranks of medical science, and that is, that this congress petition our Government to establish on a permanent basis a laboratory in which to carry on bacteriological research, the investigators to be chosen from among the leading bacteriologists of the United States, and the position not to depend on political influence; that the results of the research, combined with that proven in other lands, be published in book form and distributed to the physicians of all lands who desire them at enough above cost to assist materially in maintaining the laboratory, our Government to assume control of all examinations to practice medicine in the United States and place us on a level with other nations. It is only by a careful study of sanitary science, hygiene, and bacteriology, as they develop, that we can hope to arrive at the goal, "positive preventive medicine," where we can say that it is "Not for ourselves alone" that we are laboring, but for all mankind.

## SCHOOLS IN RELATION TO THE SPREAD OF DIPHTHERIA.

By PETER H. BRYCE, A. M., M. D., of Toronto, Canada,

*Secretary of the Provincial Board of Health of Ontario, English Secretary of the Section, etc.*

It is only the supreme importance of this subject that furnishes me with an excuse for drawing the attention of the members of this section to that which must seem to many, an old song. According to the returns of the registrar-general, almost exactly 25 per cent of the total population of England is between 0 and 10 years of age, in the proportion of 13.5 per cent between 0 to 5 years; 11.8 per cent between 5 to 10 years. Of the total school population in Ontario children between 5 and 10 years form almost 55 per cent; and I find that 31.6 per cent of the total deaths from diphtheria in Ontario occur within this period. These statistics further indicate the fact that the school population between these ages represents, at any rate in Ontario cities, nearly 18 per cent of the total population, and that the percentage of deaths of diphtheria amounts not only to more than 30 per cent of the total from this cause, but that it represents more than 2.3 per cent of the mortality from all causes in a city like Toronto. When it is further remembered that over 13 per cent of the total population is younger than 5 years, and that in almost every home whence come children of school age there are younger members at home, it will not be difficult for us to explain how it happens that nearly 90 per cent of the victims of diphtheria occur in about 25 per cent of the total population. These facts premised, and the statement of Bourges in the most recent book on diphtheria, "Il est aujourd'hui sans conteste que la cause unique de la diphtérie n'est autre que la bacille de Klebs-Löffler," it will be proper for us to examine some of the reasons for the special incidence of diphtheria among school children, especially of the age referred to, and why it is that this percentage of deaths to the whole is higher than it should be, if we remember that the deaths in 100 sick children between 0 and 5 years is 39 per cent, compared with that among those between 5 and 10, viz, 20 per cent, or much greater than the proportion of actual deaths in the first period, as compared with that in the latter. Among these reasons is the character of the bacillus. Observers have long noticed the tendency of diphtheria to develop in those houses in which organic decay was notably present, either as accumulated filth in cellars or having dark, damp, and ill-ventilated spaces under them, with decaying wood present. It has by experiment been further demonstrated that the germs will live a long time in unclean, dark, and ill-ventilated rooms, and on cloths, clothing, etc., when not exposed to fresh air and sunlight. On the other hand, it has been shown that in light, clean, and well-ventilated rooms the virus of diphtheria within a few weeks becomes largely inert or destroyed. The air likewise from sewers, whether from manholes or by defective plumbing, has, especially in the latter case, frequently been the cause of outbreaks of the disease. In all these ways diphtheria outbreaks have been produced; but the very conditions under which these outbreaks occur best illustrate how the living air of rooms, either from a patient or from the clothing of persons exposed in the sick room or other infected apartment, is daily being shown to be, of all agencies, the one which plays the most important rôle in spreading the disease. Ever since the statistics of deaths have been registered with care, as in England during the last fifty years, the incidence of what are called "communicable diseases," in the months extending from November to May, has been noticed; but it has not been until bacteriology has taught that the microbes of these various diseases can grow and multiply only in warm temperatures that the explanation of how house atmospheres, during the period of the year when ventilation is least and when children are kept indoors, have become the conditions under which infection has been most

frequent. This is due not only to the fact of the increased number of germs present in house atmospheres, but also to the fact that the conditions most favorable for producing a congested mucous membrane, thereby making inoculation possible, prevail especially in cold weather. Such are the immediate conditions favorable to the propagation and spread of diphtheria, as of other contagious diseases; but, stated broadly, the special condition is one of density of population. This, in the study of vital statistics, has formed the subject of extended inquiry by many writers. In the study of English statistics the late Dr. Farr was able to lay down a formula by which he was able from the known number of persons per acre or per square mile in any district to calculate the general death rate, which was found to conform very closely to the number of deaths from the mortality returns. Thus death rates calculated gave 18.90, 19.16, 20.87, 25.02, 28.08, 37.50, 38.74; registered gave 16.75, 19.16, 21.88, 24.90, 28.08, 52.49, 38.62. These studies were of course made where sewerage and water supply and other sanitary conditions were largely the same. The ill effects of increased aggregation of population have further been found to be much greater in the earlier years of life. Thus, from the thirty-fifth English annual report, persons to a square mile, 16.6, 379, 4,999, 65,823; death rate at all ages per 1,000, 16.94, 21.90, 28.02, 38.67; death rate under 5 years, 37.80, 47.53, 82.10, 139.52. The last figures in the list refer to the Liverpool district.

In a remarkable paper published in 1888 by Dr. J. B. Russell, medical health officer for Glasgow, this law has been illustrated and refined in a most remarkable manner by applying it to the relation between the size of the house and the general death rate. He compared the twenty-four districts into which Glasgow is divided and obtained the following results:

| Size of house.    | Percent-<br>age of<br>popula-<br>tion. | Deaths<br>per<br>1,000. | Size of house.    | Percent-<br>age of<br>popula-<br>tion. | Deaths<br>per<br>1,000. |
|-------------------|----------------------------------------|-------------------------|-------------------|----------------------------------------|-------------------------|
| One room .....    | 24.7                                   | 27                      | Four rooms.....   | 6.1                                    | 4.3                     |
| Two rooms.....    | 44.7                                   | 47                      | Five rooms.....   | 7.1                                    | 3.3                     |
| Three rooms ..... | 16                                     | 13                      | Institutions..... | 1.4                                    | 3.2                     |

The one and two roomed houses were commonly what are known as "made-down" houses, i. e., parts of large houses divided into many rooms rented separately. He found further the following relative to deaths from special diseases per 1,000 of population:

|                                                      | One and<br>two<br>roomed<br>houses. | Three and<br>four<br>roomed<br>houses. | Five<br>rooms and<br>upward. |
|------------------------------------------------------|-------------------------------------|----------------------------------------|------------------------------|
| Zymotic diseases.....                                | 4.78                                | 2.46                                   | 1.14                         |
| Acute diseases of lungs (including consumption)..... | 9.85                                | 6.89                                   | 3.28                         |

These remarkable statistics, from the standpoint of causation, are further illustrated by the experiments of professors of Carnelley and Haldane, published in the Transactions of the Royal Philosophical Society :

|                                                  | One-roomed houses. |          |           |                       | Two-roomed houses. |           |           |                          | Houses of four rooms and upward. |           |           |           |
|--------------------------------------------------|--------------------|----------|-----------|-----------------------|--------------------|-----------|-----------|--------------------------|----------------------------------|-----------|-----------|-----------|
|                                                  | Cases.             | Low-est. | High-est. | Aver-age.             | Cases.             | Low-est.  | High-est. | Aver-age.                | Cases.                           | Low-est.  | High-est. | Aver-age. |
| Persons per house (per room in last class) ..... | 29                 | 2        | 10        | 6.6                   | 13                 | 4         | 10        | 6.8                      | 18                               | 1         | 3         | 1         |
| Space per person .....                           | 29                 | 104      | 528       | 212                   | 13                 | 148       | 395       | 249                      | 18                               | 391       | 4,206     | 1,833     |
| Temperature (°F.) .....                          | 21                 | 43       | 61        | 55                    | 9                  | 50        | 59        | 53.5                     | 13                               | 42        | 63        | 54.5      |

Of course it is hardly necessary to remark that the sanitary conditions in certain tenement houses, even where population is dense, may be much better, and the mortality in them even be lower than in the small crowded houses in country places; but on the whole the broad principles already enumerated are found to hold good, judged by results. Keeping these facts fully in view we may now turn to the examination of the spread of zymotic diseases by means of the public schools in Ontario. From time to time examinations of the public schools of some of the Canadian cities have been made, notably at times when diphtheria has been prevalent in them. I am not in possession of the statistics relative to the cubic air space of all Ontario public schools; but statistics published several years ago gave the following figures for Hamilton schools, viz :

*Floor space.*—Minimum legal space: 12.32 square feet, 120 cubic feet. Actual space from seat space: 10.7 square feet, 107 cubic feet. Floor space from actual attendance: 12.7 square feet, 127 cubic feet.

These latter facts showed that the influences deciding the number of organisms were not those of temporary cleanliness, but that the influences at work have a gradually cumulative effect. These influences have been fully investigated by Emmerich, of Leipzig, who made a large number of analyses of the materials in the space between the floor of a room and the ceiling of the one below. To use his own words, he showed "there exists nowhere in nature, not even in the neighborhood of human dwellings, a soil so highly contaminated with nitrogenous organic substances and their decomposition products as the damping material

under the floor of dwelling rooms." He showed further that the carbonic acid resulting from organic decomposition in the air of empty rooms actually increased, although all other sources of carbonic acid were excluded. He further examined these materials in a prison at Amberg, in which had occurred persistently for years epidemics of croupous pneumonia which had attacked every seventh person and killed every twentieth prisoner. He not only found this material full of organic matter as usual, but also discovered Friedlander's pneumococcus in enormous numbers. The effect of this filth in pneumonia increases from 3.5 per 1,000 in the better houses to 6.6 in the three-roomed and 12.5 in the one and two roomed houses. The laws, which both from statistics and experiment are thus shown to govern mortality rates, are evidently dependent for their operation upon the fact that a house atmosphere, even at its best, is different from that of the external air in (1) its normal constituents, (2) its contained microbes, (3) its gases of decomposition, whether arising from the waste products of animal life or of dead organic matter, (4) its relative humidity, (5) its unequal distribution of temperature, thereby producing especially drafts. In this table the relative purity of the air in the better class of houses is admirably illustrated. It is of still more interest for the purposes of our subject to compare the carbonic acid and number of bacteria in the rooms with their amounts in the air of public schools. To make the difference still more evident it must be remembered that schools are occupied but six hours, while the houses are constantly occupied. Still greater differences are seen in the two classes of schools, the one being naturally ventilated by means of fireplaces, open windows, and ventilators in the ceilings, while the others were ventilated by means of fans over hot pipes. Thus, referring to the tables, it will be seen that while the number of bacteria in a liter of air in one-roomed houses averaged 60, that in naturally ventilated schools averaged 152, or two and one-half times as many, while that in the best ventilated schools was 18, or twice the number in four-roomed houses and upward. Further investigations were made into the source of the bacteria, and it was found that the bacteria in the air of a room were not materially increased by the presence of a large number of persons in a crowded room during a single lecture; neither did they come from the outer air introduced, it being relatively free from germs during these winter experiments. It was therefore concluded that the microbes came from the floor and other parts of the rooms. This was shown to be the case, and that their numbers largely depended on the cleanliness of the rooms. The schools were classified according to their length of time since construction, with the following results:

|                              | Number<br>of cases. | Micro-<br>organisms<br>per liter |
|------------------------------|---------------------|----------------------------------|
| Opened before 1866.....      | 7                   | 211                              |
| Opened before 1875-1880..... | 20                  | 150                              |
| Opened before 1884-1885..... | 5                   | 38                               |

I was recently called in to examine the sanitary condition of the public schools of one of our cities, and found the cubic air space on the average to not exceed 200 cubic feet per pupil, and this in two-story buildings. What this means in the matter of density of population is seen in the following figures: In a square acre there are 43,560 square feet. In a square mile there are 27,878,400 square feet. In a room 10 feet high, and allowing 200 cubic feet space to a pupil, the floor space for each pupil is 20 square feet. In the most densely populated Liverpool district, already referred to as having a death rate per 1,000 of 38.67, and of children under five years of 139.52, the population per square mile was 65,823, or that of these schoolrooms is twenty-one times as great. But it is practically double this in buildings of two stories, for without special ventilation the air of the two floors

is common to all the children. Without, however, pursuing this calculation any further, it becomes abundantly plain that in the limited amount of air of a school-room we have present a condition wholly opposed to the process of infinite dilution which is constantly going on in the outer atmosphere, and that any deleterious materials present in the air of schoolrooms has an opportunity for producing most certainly their evil effects. We have first of all, in naturally ventilated and crowded schools, a great increase of carbonic acid, amounting, even in rooms with an air space of 300 cubic feet, to 15 parts in 10,000, with a proportionate increase of organic matter. Extended most recent experiments by Merkel in Germany and by Haldane in England, referring to the effect produced by such air, force the conclusion that they are on the one hand due directly to the poisonous effects of an excess of carbonic acid and on the other to the absence of the normal amount of nascent oxygen necessary for oxidization of the blood. That these poisonous effects by directly depressing the system leave it an easier prey to specific bacterial poisons may naturally be inferred; but we now are in possession of experiments on animals which give direct proof of the fact. Roger has shown that the rabbit, which is naturally immune to symptomatic anthrax, quickly succumbs to the disease if at the same time there is injected a sterilized culture of *bacillus prodigiosus*. Chantmesse and Widal have found that a laboratory culture of the typhoid bacillus, which had lost all its virulence and was entirely without effect upon guinea-pigs, proved to be extremely fatal when the vital tone of the animal was lowered by a previous injection of a culture of *proteus vulgaris*. The virulence thus acquired became exceedingly intensified by further passage through animals. It has been shown, also, that physical conditions affect the power of resistance in animals. White rats, which are naturally immune to anthrax, easily contracted the disease when previously exhausted by being compelled to turn a revolving wheel. Sheep, which are naturally immune to anthrax, contract it when they have been artificially chilled. Anæsthetics have been found to act in a similar way. Platania produced anthrax in naturally immune animals (dogs, frogs, and pigeons) by inoculating them when under the influence of curare, chloral, or alcohol. In the altered relative humidity of the air of rooms in winter we have, however, what I believe to be a potent factor in the inoculation of children with the germs of diphtheria and other diseases of the respiratory mucous membrane. Everyone is familiar with the disagreeable sensations experienced in rooms heated by hot-air furnaces where no means is provided for the supply of moisture. I am not aware of any extended experiments on the subject, but the following is sufficient for purposes of illustration:

In a paper on the ventilation of schools, by Dr. J. J. Cassidy, presented several years ago to the Ontario Health Officers' Association, I find the following condition given of one of the best constructed, ventilated, and heated schools in Toronto:

January 26, 1887, 3:45 p. m.: Examination of the ventilation of Brock avenue school. Upper room (girls), cubic measurement, 10,786 feet; persons usually present, 59; cubic space per head, 183 feet; temperature, 67°; hygrometer, D. B. 67°, W. B. 53½°; R. H. 41½ anemometer; size of inlet, 4 square feet; air entering per minute, 266 linear feet; air entering per hour, 16,560 linear feet; cubic feet of air entering per hour, 66,240; number of changes per hour, 6.1; door closed and found windows closed; test of air by the senses, not close.

The mere amount of relative dryness in a schoolroom occupied by children is, however, no index of the evil influences of the air on the mucous membrane, since the exhaled moisture produced in a room filled with little children notably increases that of the room, but only by a process of drying out of the mucous membrane similar to that by which the evaporating pan is emptied of its water; the dry air, constantly inhaled, passes over the mucous membrane and abstracts an amount of vapor equivalent to about one-fiftieth of its volume, the air always being saturated when exhaled from the lungs. If 500 cubic feet of air be taken as the average

amount expired by a person in 24 hours, it is apparent that 10 cubic feet of an atmosphere consisting wholly of aqueous vapor is exhaled. It can readily be understood, therefore, how, in a schoolroom with 50 pupils, having an average air space per capita of 200 cubic feet, an enormous evaporation is constantly going on from mucous surfaces, when with this addition the air of the room, as in the examination given, has less than 50 per cent of saturation. It is manifest that if the normal air of the room has an average humidity of 75 per cent, or is three-fourths of saturation, it will extract very much less moisture than if at only 25 per cent of saturation. We have, however, to look to the contamination of the air with the specific virus of disease if we desire to explain the real and immediate cause of the spread of diphtheria and similar diseases by means of schools. I have already referred to the relative purity of external air as compared with that of house atmospheres. This may be illustrated by a comparison of the results obtained by Percy Frankland, F. C. S., in a suburb of London. Taking several days' average, he found 9,800 microorganisms per cubic meter of air which were mostly molds. From the experiments on the air of houses and schools already given I take the figure of the number of microorganisms in the air of a school of average cleanliness, naturally ventilated, and find it to be 124,000, and in the cleanest of mechanically ventilated schools, taken from 22 in all thus ventilated, there were 3,000 microbes per cubic meter. Where there are no such enormous number of microbes in school air as compared with outside air, the relative dangers would be proportionately great in the case of the school, from the fact that the same air is breathed again and again, if not by the same person, then by others, the ratio of change, even with good ventilation, as compared with the slightest breeze, being as 1 to 2,500.

But I need not multiply by illustration the dangers to which I have referred. Only one word need be said with regard to the conclusions to be drawn from them, which may be summed up as follows: (1) Diphtheria in houses is an intensely infectious disease. (2) It is a disease capable of a very mild character in some cases, while still retaining for several weeks in such patients the ability to transmit the infection and produce cases of extreme malignity. (3) It is a disease specially influenced, as regards its infectiousness, by the character and thoroughness of local treatment, and by the frequency with which the air of a sick room is changed. How this latter is true is shown by the effects on the number of microbes in mechanically ventilated schools. (4) It is a disease peculiarly liable to attack with malignity children under 10 years of age, but causes relatively fewer deaths than scarlatina among children under 3 years. (5) It is a disease the germs of which have, when hidden away in damp, dark spaces, where dead organic matter is present, a capacity for prolonged resistance to destructive influences. (6) It is a disease whose germs are weakened in their virulence by free exposure to sunlight, moisture, and free air, and these may be completely destroyed within a few days. (7) It is a disease which does not produce epidemics through the medium of public water supplies. (8) It is a disease which may be introduced into houses from defective sewers and bad plumbing; but epidemics in a series of houses on a street, or in a town or city, are never produced except by direct communication and direct infection; and this method of propagation has fresh scope and produces its most potent influences through the medium of public schools, and by persons and children visiting infected houses, and by persons from infected houses visiting in healthy homes. (9) It is a disease peculiarly frequent and fatal in the latitudes lying between the Ohio River and the northern limits of settlement in Canada. (10) It has no special habitat except that it is peculiarly a house disease, and finds its greatest opportunities for spreading in damp and cold climates, where the temperature makes people close their houses to natural ventilation, and where artificial heating is specially resorted to.

## MEDIDAS QUE DEBEN TOMARSE PARA IMPEDIR EL DESARROLLO DE LAS ENFERMEDADES TRANSMISIBLES EN LAS CIUDADES.

Por el Dr. J. E. MONJARÁS,

*Inspector General de Salubridad Pública en el Estado de San Luis Potosí.*

El aislamiento, la desinfección, el saneamiento y la energía de la policía sanitaria, son los mejores medios para impedir la propagación de las enfermedades infecciosas en las ciudades.

La primera providencia que las autoridades deben tomar para mejorar el estado de insalubridad de una ciudad, es el aislamiento de las enfermedades infecciosas. El aislamiento puede ser individual, el que se dirige sobre el individuo solo colocado entre su familia; ó bien es colectivo, reuniendo en un mismo local, hospital de aislamiento, á los enfermos atacados de la misma enfermedad contagiosa.

El aislamiento en la familia se obtiene colocando al enfermo en la pieza más amplia de la casa, mejor ventilada, y alumbrada por el sol; dedicando al enfermo el número de personas estrictamente necesario para su asistencia, escogiéndolas, si fuere posible, entre las que hayan tenido un ataque anterior de la misma enfermedad; prohibiendo el contacto mediato ó inmediato de las demás personas que no esten comprendidas en estas indicaciones; dedicando para la asistencia del enfermo los objetos necesarios para su servicio, que solo entren en contacto con él y con las personas que le sirvan; desinfectando en fin en la pieza misma del enfermo ó en otra contigua dedicada también á su servicio, todo lo que tenga que salir ó ser sacado fuera de estas piezas, tanto las personas como los objetos. La ropa que ha servido al enfermo y en general todo lo que sea susceptible de lavarse será empapado en una solución al 1 por mil de bicloruro de mercurio, hervido durante media hora y en seguida enjabonado con 20 gramos de jabón de potasa por 10 litros de agua.

Para cumplir con todas estas medidas basta la autoridad del médico asistente y la buena voluntad de la familia.

Después de haber obtenido el aislamiento individual, las autoridades deben preocuparse del colectivo reservado á aquellos desgraciados que en sus casas no tienen ciertas condiciones higiénicas para efectuar el individual. El colectivo está encomendado á las autoridades y por él debe comenzar la activa intervención que la autoridad debe tomar para sofocar cualquier epidemia y prevenir en lo futuro el desarrollo de otras.

Demostrado está hasta la evidencia: 1º, que el aislamiento colectivo no aumenta la mortalidad entre los aislados, y 2º, que empleando ciertas precauciones de desinfección, las colectividades de enfermos infecciosos en hospitales de contagiosos, no crían focos de infección nocivos á los vecinos como se pudiera suponer.

Demostrado lo está igualmente hasta la evidencia, tanto por la experiencia como por la estadística, que los enfermos infecciosos atendidos en casas reducidas sin buenas condiciones higiénicas en medio de sus familias, en la necesidad de llevar vida común con ellos, constituyen muy activos focos de infección que propagan rápidamente una enfermedad epidémica. Se impone pues desde luego la necesidad de destinar un local con condiciones á propósito para aislar á todo individuo que atacado por una enfermedad trasmisible, no pueda aislarse convenientemente ni de su familia ni de los vecinos, empleando, si es necesario, la fuerza de la autoridad para verificar su aislamiento, y haciéndolo con las precauciones que para el caso se indican.

Una vez estudiada la cuestión del aislamiento individual, debemos resolver la mejor manera de practicar el colectivo, por pertenecer exclusivamente á las autoridades, pues el primero aunque pertenece también á ellas, solo los señores médicos pueden hacer que se realicen, empleando en cada familia todos los medios

imaginables para persuadir las de los beneficios que resultan de su práctica, á la higiene privada y aún á la higiene pública, y esto es tan cierto, que en caso de resistencia podría ponerlo en conocimiento de las autoridades y aún recurrir al apoyo de la fuerza pública.

Las autoridades deben dedicarse pues á resolver esta cuestión: ¿Cómo se debe proceder al aislamiento colectivo? (1º) ¿Es preciso crear un hospital dedicado exclusivamente á abrigar á los enfermos infecciosos? (2º) ¿Es preciso destinar en un hospital general pabellones especiales? (3º) ¿Donde se pueden colocar estos hospitales especiales?

Dujardin Beaumetz, dice á este respecto:

En la larga y notable discusión hecha por Jauvel y Vallín en el Congreso Internacional de Higiene de 1878, encontramos las conclusiones siguientes que responden absolutamente á las diversas cuestiones que se acaban de proponer: (1) El aislamiento que más se acerca á la perfección, es el obtenido por medio de un hospital dedicado á una sola enfermedad ó á varias enfermedades infecciosas, pero tratadas en pabellones separados. Es también el más costoso y el más difícil de organizar. (2) Un pabellón distinto y perfectamente aislado de un hospital general, da una seguridad menor, pero aún suficiente. (3) La instalación es notablemente más fácil: Conservicios especiales sin comunicación con el resto de los edificios en medio de los cuales están colocados. (4) En cuanto al aislamiento en salas reservadas simplemente, contiguas á los servicios generales, es mejor sin duda que la promiscuidad, pero es de ordinario ilusorio y da una seguridad engañosa.

Será preciso pues, en cuanto sea posible, crear hospitales para las principales enfermedades infecciosas; á estas conclusiones llega Chantemps en su memoria presentada al Consejo municipal relativo á hospitales de aislamiento.

Queda por tratar un último punto práctico, relativo al aislamiento de los enfermos contagiosos, y es la manera de trasportarlos de sus casas al hospital.

No basta destinar para los enfermos contagiosos un hospital de aislamiento, es preciso aún trasportar estos enfermos á los hospitales é impedir que por su transporte el enfermo se convierta en un agente activo para la propagación de la enfermedad infecciosa que padece.

Para obviar todo inconveniente es preciso crear un servicio de transporte para los enfermos que se hará en coches especiales destinados exclusivamente á este objeto; dos son suficientes.

Estos coches deben ser desinfectados después de cada viaje y estar siempre á la disposición de cualquiera persona atacada de enfermedad infecciosa ó contagiosa.

Cualquier coche puede servir para el objeto; pero los modelos que se han adoptado por Jancenus en Bruselas, y de los cuales acompaño una fotografía, satisfacen perfectamente las exigencias higiénicas y económicas que demanda este servicio.

#### DESINFECCIÓN.

Una enfermedad infecciosa puede propagarse: (1), por el enfermo mismo y sus deyecciones; (2), por los cadáveres; (3), por los alimentos y objetos que han servido al enfermo; (4), por las personas en contacto con él; (5), por la pieza y casa del enfermo.

Para la desinfección se deben tener en cuenta todas esas consideraciones y las medidas deben referirse á, 1º, cuidados minuciosos de limpieza en el enfermo, en su pieza y en los objetos que se encuentren en contacto con él; 2º, frecuente renovamiento del aire de la pieza; 3º, la destrucción de los gérmenes infecciosos.

Los cuidados de limpieza consisten en lavar varias veces en el día al enfermo, cambiarlo de ropa cada vez ó lo mas frecuentemente posible. Limpiar las piezas con jergas mojadas en soluciones antisépticas al 5 por ciento de sulfato de cobre por ejemplo, teniendo cuidado de hervirlas en seguida en agua durante media hora.

La destrucción de los gérmenes constituye la desinfección propiamente dicha en un enfermo, esta puede ser externa ó interna.

Desinfección externa del enfermo. Siempre que el estado del enfermo lo permita, se deben ministrar baños generales ó abluciones con esponja, empleando la solución de 1 por mil de bicloruro de mercurio ó la de 2 por ciento de ácido fénico, etc. Los cabellos deben ser cortados así como las barbas y el bigote, teniendo cuidado de mandarlos quemar. Ningún enfermo curado deberá volver á la vida común antes de haber tomado á lo menos tres baños jabonosos.

#### DESINFECCIÓN INTERNA.

Cualesquiera que sean las ideas que dominen con respecto á la naturaleza de las enfermedades infecciosas, todos están de acuerdo en que es preciso evitar las indigestiones y fermentaciones del tubo digestivo que predisponen y favorecen poderosamente el desarrollo de todas las enfermedades transmisibles.

Desde que por los trabajos de Pasteur, de Chamean, Toussaint, se sabe á que punto las diferencias de medio de culturas modifican la actividad y vitalidad de los microbios patógenos, se está autorizado á buscar qué sustancias producen la antisepsia del tubo intestinal sin perjudicar á la economía.

La boca es la puerta de entrada y el foco de cultura de casi todos los gérmenes que existen en el aire. Es difícil que estos gérmenes penetren directamente en las ramificaciones brónquicas; se les encuentra sin embargo, pero casi todos son detenidos por la estrecha abertura de la laringe y aún antes de la laringe por las mucosidades que tapizan las fosas nasales, la boca, las amígdalas y la faringe.

Gran número de estos gérmenes son tragados con la saliva y destruidos por el jugo gástrico cuando está normal; algunas veces sin embargo, la infección de la economía tiene lugar por las vías digestivas; pero frecuentemente encuentran en la boca misma, sobre todo cuando está mal cuidada, á la vez un medio de cultura y una estufa de incubación. En ella se desarrollan entonces esperando que haya una puerta de entrada directa ó una disminución de resistencia local ó general, para invadir el órgano más fácil y propagarse por toda la economía.

Basta recordar que Roux y Yercin en sus bellos estudios sobre la difteria, han examinado las mucosidades bucales de 45 enfermos de un hospital y atacados de de otro mal que la difteria; en quince ó veinte han encontrado la forma atenuada del microbio diftérico que puede tomar de nuevo su virulencia en condiciones más favorables. Anunque en este hospital, los diftéricos están aislados en un pabellón especial, se comprende que algunos gérmenes se encuentran en el aire. Los mismos autores han examinado la boca de sesenta niños de la Normandía en la playa del mar, en una localidad donde hacía largo tiempo no habia habido difteria, y veinteicinco presentaban en la boca el bacilo pseudo-diftérico.

El papel de estas infecciones secundarias de origen bucal en el curso de enfermedades ya graves por sí mismas (fiebre tifoidea, tifo-pneumonia, pleuresia aguda) es ciertamente considerable y la cuestión merece ciertas investigaciones. Ya que esta infección sea secundaria ó primitiva, la indicación profilática es la misma; es preciso practicar la antisepsia de las fosas nasales, de la boca y del fondo de la garganta en sus pliegues por medio de lavados repetidos y prolongados, así como en los dientes por el cepillo.

Estos lavados pueden ser hechos con el agua adicionada de tinturas aromáticas donde predominen las esencias de canela, limón, badiana, etc., de los cuales Chamberland, Codeas y Meunier, demostraron hace poco tiempo las propiedades antisépticas. Sería preciso añadir en ellas naftol, salol ó ácido fénico que no son sustancias tóxicas ni capaces de alterar el esmalte de los dientes, y sí pueden contribuir á la destrucción de los gérmenes.

La siguiente fórmula que ha recomendado Dujardin-Beaumetz, me ha dado muy buen resultado: Agua destilada, 1,000 gramos; ácido bórico, 12.50 gramos; timol, 0.25 gramo; ácido fénico, 1 gramo; tintura de menta, XX.

Para las narices nada es superior á la solución de ácido bórico al tres por ciento, aspirado de manera que penetre hasta la faringe nasal.

Es evidente que para hacer eficaces tales lavados en la forma de gargarismos, deben ser repetidos varias veces por día de preferencia con líquidos calientes y ser bastante prolongados, para que el contacto con los puntos sospechosos dure cinco minutos ó más. Si estos cuidados no pueden ser tenidos todos los días rigurosamente por las personas sanas, particularmente al despertarse y al acostarse, lo que es muy fácil, á lo menos impónganse á los primeros síntomas de cualquiera enfermedad febril ó cuando haya catarro.

En cuanto á la desinfección intestinal, se puede obtener empleando diariamente de 25 á 50 centigramos de salol, sustancia que no perjudica al organismo aunque se use por largo tiempo.

Todas las secreciones de los enfermos deberán recibirse en una vasija (bacinilla ó escupidera) llena hasta el cuarto de su capacidad con una solución de sulfato de cobre al 5 y 1 por ciento de ácido clorhídrico; en seguida se les verterá en las letrinas.

También es necesario desodorizar y desinfectar estas evacuaciones que son una causa de contaminación del aire, del agua, y en general de todo lo que tocan; así es indispensable neutralizarlas antes de arrojarlas á los inodoros ó á los albañales, donde sus gérmenes podrían germinar. Si es verdad como lo ha dicho Budd que una sola evacuación tifoidea puede afectar la red de albañales de una gran ciudad. ¿No es necesario destruir los gérmenes patógenos que ellas contienen antes de arrojarlos á los inodoros ó á los albañales de la calle?

La desodorización y desinfección de las evacuaciones es algunas veces muy difícil sobre todo en ciertas enfermedades donde su putrefacción alcanza en el intestino un grado extraordinario; basta citar como ejemplo la fiebre tifoidea, la disenteria crónica, etc.

La desodorización más activa es la que produce el cloruro de zinc á la dosis de cinco partes por mil; hace desaparecer inmediatamente el olor; es al mismo tiempo á esa dosis un verdadero desinfectante; pero su manejo es algunas veces delicado, por eso aconsejamos de preferencia la solución de sulfato de cobre que indicamos y que produce el mismo efecto.

#### DESINFECCIÓN DE LOS VESTIDOS, DE LA ROPA Y DEMÁS OBJETOS EN CONTACTO CON LOS ENFERMOS INFECCIOSOS.

De nada sirve aislar los enfermos sospechosos, purificar los lugares que habiten, impedir que el aire contaminado se esparsa al exterior, si no se desinfecta minuciosamente la ropa y los vestidos que ha ensuciado. Todo el mundo conoce la frecuencia de los casos de viruela, de escarlatina, de difteria, de fiebre tifoidea, de tifo, de cólera, observados en las personas que lavan la ropa sucia que proviene de los hospitales donde reinan estas enfermedades.

En muchos hospitales ingleses se destruyen por el fuego los vestidos y ropa llevados al hospital por un enfermo atacado de una enfermedad transmisibile. En Lóndres se ha propuesto cerrar momentáneamente, mediante indemnización, los talleres de ropa ó despedir á las costureras atacadas de enfermedades contagiosas ó asistiendo en su domicilio un caso de este género. En el Congreso de higiene de París en 1878, el Dr. Smith señalaba un caso de fiebre tifoidea, transmitida á un niño de ilustre nacimiento, por un vestido de baile que el obrero había cocido y ajustado en la pieza, y casi sobre el lecho donde dormía uno de sus niños atacado de esa enfermedad.

Dos medios nos parecen tener una superioridad incontestable para la desinfección: el calor y las fumigaciones de ácido sulfuroso; el cloruro de cal, el cloruro de zinc, las fumigaciones de cloro, de cinabrio, etc., quedan en un lugar inferior.

Estudiaremos en seguida cada uno de estos medios de desinfección bajo el punto de vista de sus aplicaciones y de su modo de empleo.

Insistiremos aquí sobre la diferencia de acción del calor, según que es seco ó húmedo.

He aquí los resultados que los experimentadores han obtenido, según que hayan empleado el calor seco ó húmedo: (1) Las bacterias desprovistas de esporos no pueden soportar durante una hora y media la exposición á un aire caliente de 100° centígrados. (2) Los esporos de la podredumbre no son matados sino por la exposición durante una hora y media al aire calentado á 110° ó 115° centígrados. (3) Los esporos de bacilus no son destruidos sino por la permanencia de tres horas en una atmósfera de 140° centígrados. (4) El calor húmedo bajo presión destruye á 115° centígrados las bacterias y esporos más resistentes.

Haciendo aplicaciones en la práctica de estos datos, se hace preciso la resolución de las dos cuestiones siguientes:

(1) ¿Qué temperatura pueden soportar impunemente las materias de los vestidos y los tejidos?

(2) ¿Cuales son los aparatos que permiten hacer la desinfección por el calor?

#### ACCIÓN DEL CALOR SOBRE LOS TEJIDOS.

De una manera general los tejidos de lana se alteran más rápidamente que los de algodón. Es casi imposible conservar á los tejidos de lana la blancura que tenían cuando nuevos; pero una exposición durante dos horas á 110° no les da un tinte más amarillo que el que adquieren después del primer lavado por el agua caliente.

Esto es tan cierto que sometiendo á 110° durante tres horas una pieza de franela que ha sido ya lavada con precaución, es imposible encontrar una diferencia de tinte con una pieza idéntica que no ha sido sometida á este temperatura. Sin embargo, partiendo de 115° y sobre todo de 120°, la diferencia se hace sensible cuando la temperatura ha sido mantenida á lo menos dos horas.

Es pues solamente á temperatura de cerca de 150° que los tejidos de lana comienzan á perder su resistencia.

#### ACCIÓN DEL CALOR HÚMEDO.

La inmersión en el agua hirviendo y el mantenimiento de la ebullición durante una hora, es un medio eficaz y de fácil aplicación del calor á la desinfección. Este medio excelente y de uso diario para la ropa blanca y de cama, cesa de ser aplicado para los vestidos de paño y de algodón; la lana seca muy lentamente, muchos vestidos serían deformados y deteriorados por el agua caliente; la ebullición en el agua quita toda su elasticidad á la lana y á la cerda; en fin, algunos objetos, como pieles, no pueden ser sumergidas en el agua.

Es pues indispensable recurrir á aparatos, estufas de desinfección, en los cuales se emplea el vapor de agua con presión á 115° centígrados, que no altera los tejidos y produce una destrucción segura, eficaz, y rápida (media hora es suficiente) de los gérmenes más resistentes. El mejor modelo es el que acompaña esta memoria, marcado con el número 2; puede desinfectar grandes cantidades de objetos en muy poco tiempo.

Hay otro modelo móvil que puede ser empleado de casa en casa ó trasportarse á otros lugares donde se desarrolla una epidemia.

Mas como no siempre es posible tener esta clase de aparatos por el precio subido de ellos, aunque constituyen una verdadera economía tanto por lo barato que sale la desinfección, cuanto por el poco tiempo empleado, se puede recurrir al empleo del ácido sulfuroso.

## ACCIÓN DEL ÁCIDO SULFUROSO SOBRE LOS TEJIDOS.

La combustión de treinta gramos de azufre en flor, diez de clorato de potasa y un poco de alcohol por cada metro cúbico, bastan para destruir los gérmenes más sospechosos. Lo mismo que hicimos con el estudio del calor, debemos hacerlo con el de este gas. Debemos buscar aquí ¿Cual es la acción del ácido sulfuroso producido por la combustión del azufre, en los tejidos y las partes accesorias de los vestidos, así como los objetos metálicos y otros?

Tenemos en este punto una grande experiencia, pues algunos miles de desinfecciones hemos practicado y podemos decir de una manera segura que en dosis de 30 gramos el azufre quemado por metro cúbico no produce las más veces ningún cambio en la consistencia de los tejidos de lana y de algodón, ya estén ó no mojados.

No es dudoso que empleando mayores dosis, se llegará á destruir la solidez de los tejidos.

Con respecto á la coloración es un poco diferente: casi todos los colores claros son desteñidos, así es que muy pocos quedan fijos después de la acción del ácido sulfuroso.

A los metales los hace tomar un color más subido que desaparece frotándolos.

LA DESINFECCIÓN DE LAS HABITACIONES COLECTIVAS Y PRIVADAS DEBE PRATICARSE INMEDIATAMENTE QUE LA ENFERMEDAD HAYA TERMINADO.<sup>1</sup>

Tenemos como ejemplo un cuartel, una pieza, un dormitorio de colegio; hay que desinfectar los muros, los techos y los suelos; los mejores procedimientos son los que hacen uso de la lechada de cal recientemente preparada, ó la solución del bicloruro de mercurio al  $\frac{5}{1000}$  adicionando ácido clorhídrico al  $\frac{1}{100}$ ; para ello se debe emplear cepillos que permitan poner en íntimo contacto las paredes con el líquido, las bombas de Geneste y Herscher dan un resultado seguro en teoría, pero en la práctica casi siempre el resultado es dudoso.

La pintura con la cal, muy en boga en otro tiempo como medio de purificación de las paredes, cayó en descrédito por largo tiempo.

Los higienistas, hace poco todavía, la consideraban como un medio bastante grosero de blanquear las paredes; pensaban que no destruiría los gérmenes nocivos depositados sobre las paredes de los locales habitados; juzgaban indispensable, en las casas donde por economía se conservara la pintura hacerla preceder de una pulverización con una solución de sublimado al milésimo.

En fin, desde hace largo tiempo, las capas antiguas de pinturas eran consideradas como un receptáculo, casi como un foco de gérmenes antiguos, y la mayor parte de las administraciones civiles y militares han prescrito en sus reglamentos, raspar precisamente las capas antiguas de pintura.

Las recientes investigaciones de Richard y Chamtemesse, las de Libornis, Pfuhl, de Giasa, confirmando las observaciones ya viejas de Pettenkofer sobre la acción desinfectante y microbicida del agua de cal, han venido á modificar más adelante aquellas opiniones.

La pintura con lechada de cal ha dado los resultados más satisfactorios para la esterilización, no solamente de los polvos superficiales, sino también de las capas de pintura subyacentes penetrados por el líquido empleado.

La lechada de cal se prepara con 2 kilogramos de cal recientemente apagada, bien mezclada ó deshecha en diez litros de agua decantada solamente un cuarto de hora después, cuando todas las partículas gruesas se quedan depositadas en el fondo del vaso, de tal manera, que la lechada de cal obtenida no contiene en suspensión sino partículas extremadamente finas.

<sup>1</sup> Proscribimos el uso del cloro por ser su manejo muy difícil y por que altera más que otras sustancias los tejidos y colores de los objetos.

Esta lechada de cal se manifiesta siempre estéril aunque el agua empleada no lo haya sido absolutamente y la pared en que se ha experimentado contenga un número de gérmenes muy considerable; siempre se ha encontrado esterilizada al cabo de 24 horas.

La ablución por soluciones de sublimado desde el 1 por mil hasta el 1 por ciento, adicionados de 1 por ciento de ácido clorhídrico, ha permitido comprobar á Mr. Lapanet de una manera bien clara, los resultados obtenidos por MM. Guttman y Merke y M. Bardoni Uffreduzzi, á saber que las soluciones al 1 y 2 por mil son del todo ineficaces; que las del 3 y 4 por mil no dán sino una esterilización relativa poco segura, y que se necesita una proporción del 5 por mil para destruir de una manera cierta los gérmenes contenidos en la pared.

Después de varios ensayos nos proponemos emplear el siguiente modo de preparar pintura: Agua simple fría, 5 litros; cal recientemente apagada, 1 kilogramo. Se disuelve esta mezcla, se agita, después se deja reposar un cuarto de hora. Todas las partes pesadas como la arena que recubre la porción de cal apagada, las piedras calcáreas contenidas en esta se depositan. Es inútil añadir creta, la cal es bastante. Se decanta entonces, vaciándose en un cubo el líquido que sobrenada. En cuanto á las capas antiguas de pintura no contienen sino una cantidad insignificante de gérmenes inofensivos en las condiciones ordinarias.

Los gérmenes contenidos en los polvos adherentes á la superficie, son destruidos por la aplicación de una nueva pintura con lechada de cal bien preparada.

La operación costosa é insuficiente del raspado de la pintura vieja, es pues inútil.

El modo actual de preparación de la pintura es irracional. Ligeras modificaciones hacen su empleo más eficaz, bajo el punto de vista de la desinfección más simple y menos costosa.

Para la desinfección de los inodoros hay que tener en cuenta las tres formas ó sistemas que en las ciudades se emplean. (1) Inodoro en comunicación con los albañales. (2) Inodoro de fosa móvil. (3) Inodoro de fosa fija.

Para los primeros, se deberá emplear el agua abundantemente y una solución de 5 por ciento de sulfato de cobre y 2 por ciento de ácido clorhídrico.

Con los segundos y los terceros se practicará lo mismo, pero con menos agua y más sustancias desinfectantes por ser reducidas las fosas que los forman.

#### SANEAMIENTO.

La primera necesidad que hay que llenar al ocuparse del saneamiento de las ciudades es la de proveerse de agua potable; notoria es la escasez de este precioso líquido en muchas ciudades, y sin embargo, aún en estas circunstancias, una intervención rápida y eficaz podría aumentar su cantidad.

Las autoridades se deben preocupar mucho de la instalación de pozos artesianos que debido á los progresos de la ciencia y de las artes se llevan ahora á cabo en poco tiempo. Dicho sea esto sin perjuicio de la construcción de presas ú obras especiales á cada localidad, pero que aseguren 150 á 200 litros por persona cuando menos.

Es preciso entubar el agua desde su origen para evitar todo contacto prolongado del agua con el aire, pues si bien es cierto que este elemento no contiene en las capas superiores gran cantidad de gérmenes zaptófitos ó patógenos, lo es también, que existen en las inferiores, sobre todo después del barrido de las calles, y que ellos contaminan de una manera enérgica el agua de las fuentes ó de los tubos que estan á su alcance. Evitar también y á todo precio, que las materias de los albañales ensucien estas aguas, sea accidentalmente, sea de una manera constante como sucede en las ciudades que hacen uso de agua de río ó lago para alimentación, y que á la vez dirigen á estos lugares los albañales. El agua potable cuando sea sospechosa

deberá inmediatamente esterilizarse mezclándole 40 centigramos por litro de la siguiente fórmula para las que no tengan ó tengan pocas sales calcáreas: Polvo de cal viva, 9 partes; polvo de carbonato de sosa, 5 partes; polvo de alumbre, 1 parte; polvo de sulfato de fierro, 1 parte. Mézclese bien y guárdese del contacto del aire.

Para las aguas que contengan sales calcáreas, se empleará la misma fórmula y la misma dosis sin el sulfato de fierro.

En seguida viene la necesidad de resolver higiénicamente el alejamiento de las inmundicias; para esto el agua hace también mucha falta, principalmente para los inodoros que están en relación con los albañales y que forman el sistema de *Tout à l'Égoût*.

Para los que tienen el sistema de fosa móvil, se proveerá la autoridad de uno ó más carros que á cierta hora recojan las inmundicias de los inodoros, y los transporten al local conveniente.

Lo mismo se hará con los que tienen el sistema de fosa fija, procurando substituir estos con aquellos.

Los caños públicos deben ser desinfectados en tiempo de epidemia mediante grandes cantidades de sulfato de cobre (5 kilogramos por metro cúbico de materia por disinfestar vertidos en soluciones al 5 por ciento, por la boca superior, y mediante fumigaciones de azufre hechas por su boca inferior).

Para la limpia de las calles, se deberá emplear el número de carros necesarios, de tal manera que puedan pasar tres veces por cada esquina, y obligar á los habitantes de la ciudad á que guarden la basura en sus casas, hasta que el carro pase por frente de ellas.

Se formarán cuadrillas de hombres para que limpien con frecuencia las calles, poniendo lechada de cal en la tierra donde haya materia fecal humana ó de animal.

Tanto las basuras como las inmundicias deberan ser llevadas á un lugar situado á dos kilómetros distantes de la ciudad y ser quemadas las primeras y revueltas las segundas con tierra para utilizarlas como abono.

#### POLICÍA SANITARIA.

La primera providencia que se debe tomar es aplicar con todo rigor todos y cada uno de los artículos de los reglamentos relativos á las enfermedades transmisibles; en el caso que no existan, dar disposiciones que variarán en cada ciudad pero que tendrán por base los cuatro puntos que tenemos recomendados.

Se nombrará para cada cuartel de la ciudad un subinspector, médico titulado; y para cada manzana, un manzanero encargado de la desinfección de las casas y de tomar noticias diarias de los casos de enfermedades infecciosas que ocurran, marcha de la enfermedad, condiciones higiénicas de la casa donde tal de gracia haya, elementos de la familia del paciente, y demás informes conducentes. Diariamente los manzaneros darán cuenta de lo ocurrido en su respectiva manzana al subinspector del cuartel, para que este reuniendo los datos que le trasmite el manzanero, los aprecie debidamente, rectificándolos ó ratificándolos, y dé cuenta diaria á la oficina general de higiene.

Los manzaneros son los directamente designados para la desinfección. Las sustancias con que esta deba hacerse, estarán bajo la vigilancia y distribución de los subinspectores, en un depósito que se construirá en cada cuartel y de donde se repartirán á los manzaneros, con un vale de los manzaneros conforme las necesidades que indique su papeleta. Los manzaneros recorrerán diariamente su manzana, informándose de lo que en cada casa ocurra acerca de la enfermedad infecciosa. En caso de que en una familia se encuentre un enfermo de tifo y la casa no preste comodidades para aislarlo ó no lo haga la familia, dará parte inmediatamente al subinspector, quien por medio de la policía hará que se cumpla con lo prevenido en el reglamento respectivo.

Cuando los elementos de la familia no permitan atender al enfermo convenientemente, los subinspectores lo harán trasportar en el acto al hospital de aislamiento.

Mas si solo le faltan recursos para pagar un médico y la compra de medicinas, el subinspector se prestará gratuitamente á curarlo, ministrándole por cuenta de la inspeccion los medicamentos necesarios.

Se redoblará la vigilancia de los inspectores de bebidas y comestibles, para eliminar del consumo público las substancias alimenticias sospechosas.

#### CONCLUSIONES.

- (1) El aislamiento individual deberá permitirse solo á aquellos enfermos que tienen los elementos necesarios para practicar las medidas que evitan el contagio.
- (2) El aislamiento colectivo de los enfermos atacados de males transmisibles debe ser obtenido en hospitales destinados exclusivamente á cada una de estas enfermedades ó cuando menos á un grupo de ellas; deben estar perfectamente aislados uno de otro los pabellones que contengan enfermedades distintas.
- (3) Ambos deben ser vigilados por la autoridad sanitaria y á su satisfacción.
- (4) La desinfección para que sea eficaz deberá practicarse en las secreciones de las personas, ropas, y objetos, que tuvieron contacto con él, y en la pieza y casa que habitaren.
- (5) La desinfección de los muros puede hacerse ó con bicloruro de mercurio ó con lechada de cal ó ácido sulfuroso.
- (6) Para que el sublimado desinfecte las paredes, suelo, y techo de las piezas, es preciso usarlo en soluciones al 5 por mil, adicionadas de ácido clorhídrico al 1 por ciento.
- (7) Para que el agua de cal sea eficaz se necesita que esté recientemente apagada, y que sea en la proporción de 1 por cinco partes.
- (8) El ácido sulfuroso es infinitamente menos eficaz que los dos medios anteriores y exige que el local esté precisamente cerrado herméticamente.
- (9) El saneamiento de las ciudades se arregla según las circunstancias de cada localidad, pero tiene por base: proveerla de agua potable en cantidad de 200 litros por habitante y por día, cuando menos; asear las calles y las casas; alojar de las ciudades por conductos impermeables las inmundicias antes que entren en fermentación.
- (10) La policía sanitaria para que sea eficaz debe tener por base la aplicación inmediata de las medidas sanitarias por agentes suficientemente instruidos, en número bastante según las necesidades y con facultades autoritativas que les permitan hacerse obedecer por todos.
- (11) Por último, solo los empleados sanitarios deberán practicar el aislamiento, la desinfección, el saneamiento y lo relativo á policía sanitaria.

---

#### THE EARLY DETECTION OF PHTHISIS, INCLUDING THE AUTHOR'S CONTRIBUTIONS TO DIAGNOSTIC MEANS, WITH AFTER CONSIDERATIONS OF A POSSIBLE PRETUBERCULAR STAGE.

By CHARLES DENISON, A. M., M. D., of Denver, Colo.,

*Professor of Diseases of the Chest and of Climatology, Medical College, University of Denver; ex-President American Climatological Association; Author of Climates of the Rocky Mountain Health Resorts.*

It is very generally claimed by the enthusiastic friends and reviewers of various health resorts, where consumptives are invited to seek relief through climatic influence, that the resorts are favorable if the invalid comes in the incipency of his disease. No matter what various and questionable combinations of climatic attributes exist in a given locality, the fact of an invalid coming too late, when the progress of his disease had advanced too far for recovery, is always held in reserve as a possible excuse for the death which is to take place. So everywhere is seen the importance of the early detection of phthisis, making the diagnosti-

cian's lot at the same time most important and difficult. Undoubtedly the existence of softening in lung tissue and the positive evidence of tuberculosis afforded by tubercle bacilli being found in the patient's sputum are too generally depended upon for a positive diagnosis. It ought to be the rule that conclusive evidence is generally reached and proper remedial measures, climatic and otherwise, settled upon before such serious symptoms become prominent. Thus the mastery of the disease would be much simplified. It is with a hope that my personal studies of this important problem have added something to our diagnostic resources that I am emboldened to present them, in lieu of a comprehensive essay on diagnosis. The limit of time at my disposal will be my excuse for this fragmentary method of treating this subject by presenting the following means of diagnosis which I have devised or experimented with, namely, (1) the binaural stethoscope, (2) the spirometer, (3) the manometer, (4) the diagnosis by tuberculin (Koch's).

#### THE STETHOSCOPE.

The instrument which bears my name is so well suited, when properly made, to illustrate what I consider the essentials of a perfect stethoscope that I will not apologize for enumerating here its good qualities.

*The smooth inner caliber.*—Large size and gradually decreasing from the bell to the ear ending, in imitation of the speaking tubes used for deaf persons. The law of sound is like that of light transmission, i. e., the angles of incidence and reflection are equal, and this transmission is aided by the trumpet-shaped bell and gradually decreasing size of the smooth inner surface of the tubes.

*The continuous transmission of sound.*—This must be natural; so hard rubber or celluloid are preferable to metal for the tubes, as the latter gives a high pitch and metallic quality to the sounds heard. The joints between the bells and the main tube, and between the arms and the flexible tubes, are made by the even and perfect fitting of slightly conical tubes into each other, making the whole instrument as if of one piece as far as the transmission of sound is concerned. Probably a larger part of the sound is transmitted through the stethoscopic substance than through the hollow cavity.

*The construction of the flexible tubes.*—The coiled wire for these tubes, which lines the usual rubber tubes and is itself lined with smooth, soft rubber, is made to impinge at each end of each tube against the gutta-percha, so that a nearly perfect transmission of sound is obtained. This is the part that Tiemann & Co., of New York, alone have succeeded in rightly making, and it is an important feature of my stethoscope. The cheapening of the instrument by substituting symmetrical sized in place of the original conical flexible tubes, as in the instrument now sold by Charles Truax, Green & Co., of Chicago, seems to be accomplished with the loss of a very little only of sound-transmitting power.

The ear endings as lately made are acorn shaped, with openings so turned as to be directed toward the drums of the ears. This is a compromise from what I wanted, which was to have the lower and forward side of these ear tips bulge so as to fill the space behind the tragus and leave the hole above and back immediately in front of the auditory canal. The difficulty of fitting variously shaped ears with perfectly adapted ear tips is considerable with any other than the even, conical pattern, but I think ought to be overcome.

The spring attachment to pull together the arms is purposely excessive and also adjustable, so that all the pressure of the ear tips can be obtained that the listener can stand with comfort. This much pressure is desirable for perfect transmission of sound.

*The ordinary bell endings* are as follows: The stationary bell, with slightly flaring rim  $1\frac{1}{8}$  inches in diameter, which is large enough to use in examination of infants and in the detection of valvular lesions. The medium-sized bell, which has a rim of  $1\frac{1}{2}$ -inch diameter, and sufficiently flaring to give a good impinging surface against the chest, is the size ordinarily used. The soft-rubber bell, rather thin and flexible, is intended to crowd into the medium-sized bell, giving a one-fourth-inch projecting rim of soft rubber for use on uneven surfaces, as in much emaciated consumptives.

*The large bell for stethoscopic percussion.*—This is not, as has been assumed, for use held against the chest wall, but for gathering the waves of sound emitted from the mouth during expiration while forcible percussion is being made over portions of the lung, where softening, bronchiectasis, or excavation is suspected. The concussion of the air contained in the thorax carries with it the succession, the cavernous, or the cracked-metal sounds which accompany the three above-named conditions, and by holding this large bell 1 or 2 inches from the patient's mouth, and percussing during expiration, they are distinguished better than can be done in any other way. Indeed, in thin-chested persons, with superficial excavations connected with a main bronchus, the finger-nail percussion will nicely and accurately outline the limits of the excavation. The cracked-pot or hollow sounds are altered in various ways; a slushy or succussion quality being sometimes imparted to either, according to the amount of moisture or breaking down which complicates the condition. I believe that the importance of the question of the first breaking down of lung tissue elevates this stethoscopic percussion to a first place in the art of physical diagnosis. It is certainly coëqual with any ordinary percussion, and only second, if inferior at all, to auscultation.

The test which I suggest for determining the relative perfection in transmitting power of a stethoscope is to put a watch on a show case or table, cover it with the palm of the hand, and then press the bell against the back of the hand. The clearness with which the working of the machinery is heard is the criterion of perfection in the instrument. By this test seven-eighths of the other stethoscopes sold fall short of their proper utility. The importance of depending upon an instrument as nearly perfect as possible in sound-transmitting power makes this test of a stethoscope especially valuable.

#### THE SPIROMETER.

The spirometer here described is recommended for its simplicity of construction and the ease with which the vital capacity of a child, a woman, or a strong man may be shown by it. With this instrument there is not resistance enough to the expired breath to hinder its use by anyone, and it is gauged for the accurate measurement in cubic inches of the vital capacity. It is made of a light elastic closed bag in the form of a bellows, with a top and bottom attached so that they move parallel to each other within a frame of nickel rods, each inch movement of the center recording rod being about equal to 50 cubic inches of air in the expanding

bellows. The accompanying cut gives the form of the instrument, and the annexed table gives the best records at hand for comparison of vital capacities, according to sex and height. It is to be noted (see table) that the greater capacity of the college men for increasing heights above 5 feet 7 inches simply illustrates the advantage training gives for the advanced students in such an institution.

*Standard vital capacity table.*

[Computed by Hutchinson from 5,000 observations.]

| Height.        | Males.          | Females.        | Height.        | Males.          | Females.        | 2,230 Am-herst Col-lege stu-dents' (males) gymna-sium rec-ord. |
|----------------|-----------------|-----------------|----------------|-----------------|-----------------|----------------------------------------------------------------|
| <i>Ft. in.</i> | <i>Cub. in.</i> | <i>Cub. in.</i> | <i>Ft. in.</i> | <i>Cub. in.</i> | <i>Cub. in.</i> | <i>Cub. in.</i>                                                |
| 4 7            | 126             | 88              | 5 5            | 206             | 168             | 194                                                            |
| 4 9            | 142             | 104             | 5 6            | 214             | 176             | 210                                                            |
| 4 11           | 158             | 120             | 5 7            | 222             | 184             | 224                                                            |
| 5              | 166             | 128             | 5 8            | 230             | 192             | 240                                                            |
| 5 1            | 174             | 136             | 5 9            | 238             | 200             | 256                                                            |
| 5 2            | 182             | 144             | 5 10           | 246             | 208             | 270                                                            |
| 5 3            | 190             | 152             | 5 11           | 254             | 216             | 286                                                            |
| 5 4            | 198             | 160             | 6              | 262             | 224             | 302                                                            |

As far as my own experience goes I believe the diagnostic value of the spirometer in chronic lung diseases has never yet been duly appreciated by the medical profession. It is either because spirometers have been too expensive and faulty in construction, or because the mechanical conditions due to disease and affecting the air pressure and volume within the thorax are not understood, especially the contracting or shrinkage of affected lung tissue due to nature's effort in healing, or the natural process of arrest or encapsulation of tubercular affected portions. This shrinkage or impaired movement once accurately measured by separately

taking the movements of the two sides of the chest (from the center of a dorsal spinal vertebra to the marked center of the sternum), and the proportionate data are furnished, including the spirometrical record of the individual, for computing the comparative amount of work the two lungs are doing. Thus I have formulated the following, which is submitted as a rule for determining lung ventilation: Suppose the normal spirometrical record of a patient is only half what it should be for his height, and the expansions of the two sides are as 1 to 2, then, if no defect or disease exists in the better lung, it is well to assume that the lack of ventilation in the other lung is almost complete. It is practically as bad as if there were no expansion at all of the affected side, which would surely indicate that all of the spirometrical record in that case came from the unaffected lung. With both lungs differently affected, however, the feebler lung could be said to be doing from a little up to, say, about one-third of one lung's share or one-sixth of what the two lungs together ought to do in health. In view of the various mental impressions

which the physical signs of dullness and diminished movement may cause in different observers, such a means of positive measurement of lung impairment or inactivity as the above rule and method afford should certainly be appreciated as an invaluable guide with which every physical diagnosis ought to harmonize or due explanation be afforded why it does not. The spirometer may not indicate the disease, but its use is so important that the physical examination must make clear the spirometrical record of a given patient, or that examination is untrustworthy. How important, then, that every physician, when examining a chronic lung case, should know what the vital capacity of his patient is, that he may be satisfied himself that his conclusions are correct, as well as that he may do his patient full justice.

#### THE MANOMETER.

As a means of determining the strength of the elastic lung tissue, the amount of which the spirometer has given; as a proof of the fibroid healing, which is nature's method of arrest in most lung infarctions, and in the encapsulation of tubercle bacilli, the manometer is a valuable adjunct to the physician's armamentarium. Many persons, too, with a tendency to fibroid lung shrinkage will find the

manometer to afford a means of respiratory gymnastics, which will be the better appreciated when one sees how nicely the loss or gain in respiratory vigor which is the result of any given method of treatment can be kept track of.

*Direction for using.*—After a moderate inspiration blow in the tube steadily with increasing force, same as in using a trumpet, until your full expulsive power is realized. The manometer records the elastic tension which the air cells will stand under a forced and sustained expulsion of air from the chest, as compared with the average of a healthy man. This strength is indicated on the index, i. e., the point to which the top of the mercurial column is pushed down in any instance. This is expressed in millimetres of mercury, the average for a healthy, strong man being 100 millimetres, or about 2 pounds pressure; and for women about 75 millimetres. A deficiency of, say, 30 per cent from these standards for healthy persons needs to be explained by a careful physical examination, excluding an occasional inability to appreciate how to breathe in this instrument, and it can be concluded that such deficiency indicates weakness and perhaps latent disease, especially if there is also inequality of movement of the two sides of the chest or the spirometrical record is likewise defective.

The manometer record is sometimes good in old cases of deep-seated bronchiectasis, in which the spirometer, previously described, is peculiarly diagnostic. It seems to happen this way: Toward the end of a full expiration into the spirometer, there being no resistance to the outgoing breath, such a contraction or spasm of the protective fibroid tissue around the cavity is excited that the foul contents are regularly thrown out in expectoration when that particular exhaustion of the air in the lungs is reached. Of course emphysematous persons, for whom, if the condition is recent, the manometric record is usually deficient, should not use this instrument, except simply for diagnostic purposes.

#### THE DIAGNOSIS BY TUBERCULIN.

It is not my purpose to throw undue discredit upon our means of diagnosis of phthisis in its incipency. Theoretically, so far as our text-books go, the profession may seem to be well fortified for the work, but practically, whether due to defective means, method, or conception on the part of the physician, there are too often cases of evident tuberculosis unrecognized till such a time that the most favorable season for arresting the process has already passed. Without here going into the details of the early physical signs of phthisis, it is sufficient for our present purpose to show that in these uncertain and doubtful cases Koch's new discovery, tuberculin, has the power to bring to our knowledge their true nature and extent with precision and gratifying certainty. For the proper appreciation of this wonderful power some familiarity with or knowledge of the local reaction of the remedy in tubercular lung tissue is necessary. In my report on "Tuberculin and the Living Cell" to the American Climatological Association, in 1892, I reiterated what I believed I had been the first to discover the previous year, that this reactionary effect "consists mainly in a harsh, puerile, or an exaggerated bronchovesicular breath sound, as heard with the stethoscope over the affected area. This is an exaggeration of what was heard before the tuberculin reaction, or it is heard in localities in which the breath sound was previously inaudible or very different. It is not an evanescent effect, but usually continuous, though in a lessened or lessening degree during the whole course of treatment." Sometimes this local lung reaction is very feeble, while the systemic reaction, as shown by temperature, pulse, etc., is quite marked and characteristic. The following is an excellent illustration of tuberculin diagnosis in a case where neither the physical signs nor a microscopic examination of sputum could satisfy my decided suspicion that the case was of a tubercular nature.

*Case 1.*—Mrs. K., Chicago, aged 24, married four years, height 5 feet 4 inches. No hereditary tendency to consumption. Seen one week after arrival in Colorado. Weight, 102; usual weight, 130. Gradual loss of weight since a miscarriage two years previously, after which she had influenza. While at school, aged 16, had dry cough and irritation in throat thereafter. Free from this two years in Europe, and then worse in 1889. Lately a wheezing and stuffed-up condition toward evening, sometimes had to sit up all night and frequently had to go to an open window at night during the past year. This was evidently a case of complicated asthma, for there was a considerable relief of the hard breathing on arrival in Colorado. Expectoration, dark yellow; cough, spasmodic; circulation, poor; patient, pale but catamenia regular; pulse, 94; respiration, 20; temperature, normal 10 a. m.; spirometrical record, 125; manometer, 45 millimetres; chest expansion, 2 inches, evenly proportioned to the two sides. The physical signs were not very marked. The expiration was generally prolonged. There was tympanetic resonance over left main bronchus, and cog-wheeled respiration and blowing expiration left mammary region. Feeble voice sound and broncho-vesicular respiration left apex rear. On the right there was slight dullness and broncho-vesicular breathing front and rear at apex and the voice was somewhat exaggerated in the rear. There were no bacilli in the sputum. The diagnosis was asthma and probably broncho-tuberculosis, and it was decided to test the case with tuberculin. The accompanying diagrams show the characteristic tuberculosis reaction to tuberculin, so far as the pulse and temperature are concerned, taken four times a day, according to the method I have employed for three years.

The local lung reactions were first manifest, after the  $2\frac{1}{2}$ -milligram dose, in the left mammary region, where the cogwheeled breathing was before, and on the right side, at the junction of the third rib and its costal cartilage. After the 4-milligram dose these stethoscopic signs were also noted above in both first interspaces. These sounds were accompanied, when the temperature rise was great, with decided general reactionary symptoms of slight chill, fever, malaise, and headache. The sounds, however, at first dry, became softer and less pronounced as reactionary signs subsided, till they were about gone at the 60-milligram dose, when the patient, much improved in weight, strength, feelings, and freedom from the old spasmodic coughing spells, did not react, though a rise of 10 milligrams every third day was given thereafter. Note that the dose can be increased much more rapidly in such a case than in one in which there are any advanced tubercular lesions in the lungs. In the latter condition, of course, such marked temperature reactions should not be tolerated. Note also that the general reactions, as indicated by the temperature rise, reached their maximum on the day following the injections. From this fact alone it is reasonable to conclude the general dysceosia exceeds any existing local lung lesion. I conceive that the more rapid capillary circulation in lung tissue, five times more than in the periphery of the body, may account for some of the quick reactions (in three to five hours) in tubercular lung tissue.

In my considerable experience with Koch's tuberculin, and lately with Kleb's tuberculo-cidin, this gratifying diagnosis and result has been exceeded for certainty of effect by only two cases, which are worthy of more extended mention than we can give them here.

*Case 2.*—Dr. G., of Vermont; aged 38. Positive inheritance, his mother and five sisters, out of seven in family, having died of consumption. His wife had died of tubercular meningitis three years previously, from whom he may have been infected, as the disease was general in her. He had had a seton put in the back of his own neck twelve years ago for meningitis, which seemed to be relieved, and eight years ago had suffered fracture of the ribs, with septicæmia resulting. Three years ago had la grippe and double pneumonia, more severe on the right side, and was sick six months; came then to Colorado, and gained 17 pounds in as many days. November 20, 1892, after a cough in Vermont, had what was termed basal meningitis and has been sick ever since. Headache continuous; and lately very severe up to April 20, 1893, when in Colorado the following described relief came: There was no expectoration to examine, and only slight dullness, lessened movement, increased fremitus, exaggerated voice sounds, and broncho-vesicular breath sounds on the right side. The temperature, pulse, and respiration were found to be regular for two days— $98.5^{\circ}$  F., 60, and 20, respectively—when 1 milligram of tuberculin was injected. The genuine diagnostic reaction did not start till twenty-two hours afterwards, and then was chiefly general and not local in the lung. It was manifest by temperature,  $100.5^{\circ}$  F., and pulse, 82 to 90, and continued more or less for about fifteen hours, during which at one time he vomited. The day following its cessation a slight increase in dose of tuberculin was given, which

was followed, in four to six hours, by a slighter reaction than before. By that time the headache had entirely ceased, and the patient, who had been confined in bed for four weeks, was enabled to be daily out of doors with comfort. The constriction about the base of the brain, which was marked with the first reaction, gradually disappeared. In less than four weeks, after reaching a dose of 13 milligrams, and feeling well able to do so, the doctor returned to his Vermont home, where he has been engaged in practice since, enjoying, so he says, good health. This remarkable case is given as possibly the first diagnosis of tubercular meningitis by tuberculin on record.

*Case 3.*—A case of tubercular arthritis in both knee joints in a young lady of 28, who was taken thus while nursing a sister in an Eastern sanitarium who died of tuberculosis of the bones of the pelvis and spine. Three years afterwards, after having tried in hospital several kinds of surgical treatment, the patient referred to submitted to a test with tuberculin at my suggestion. She had lost the use of her limbs and was compelled to use a wheel chair for locomotion. The reaction at the 3, 6, 7, and 9 milligram doses of tuberculin were both general, i. e., headache, malaise, some fever, and general distress, and somewhat local in the left lung, where at age of 16 she had suffered some slight disease. Seven months after this diagnosis an attack of la grippe seemed to center the tubercular poison in glands on the left side of the neck, which, being removed, showed tubercle bacilli in giant cells in the center. This confirmation of the previous diagnosis led to a continuance of the tuberculin treatment in Colorado, from October, 1892, to May, 1893. The result has been successful, for the young lady, now in Vermont, enjoys excellent health and walks considerable distances without her crutches.

Other instances of decided diagnosis of tuberculosis, if cited, would include two cases of tubercular ulceration of the colon; lymph-adenoma, with general glandular involvement; scrofulous cases (glandular), and supposed pulmonary fibroses. An important consideration to be drawn from some of the above and other of my cases is that there is an active tubercular stage, pretubercular, if you wish to call it so, before the bacillus of tubercle makes its appearance as a factor in the case, so far as we are able to judge. I do not refer to such manifestly tubercular cases as where the full clinical picture of an acute phthisis is given, although the bacillus of tuberculosis can not be microscopically demonstrated in the sputum; perhaps as with a young lady patient I have in mind, whose expectoration was loaded with spores one week and the next gave 50 bacilli to the field, the first found in her case. Nor is reference intended to be made to other cases where active tuberculosis can be inferred as going on away from the bronchial tract, and the more acute and septic on that account; i. e., because the bacilli are not thrown off. But reference is intended to those intricate, slowly acting blood changes, which come under the classification of dyscrasiæ, which may be, for all that we know, the *sine qua non* of the existence of the bacillus of tuberculosis, that state which may indicate the more or less complete annihilation of the body's natural antagonism to this particular foe. If our judgment and means of knowing the first appearance of the bacillus are not wholly at fault, then there is certainly enough in this idea of a definite pretubercular state to bring great credit upon him who will elucidate this interesting and important problem.

Among the phases of this subject to be solved the following appear to me to be urgent: (1) Minute explanations, on pathological grounds, of the adenoid growths in the region of the third tonsil, such as have been known to be removed *ad infinitum* by specialists. No microscopic evidence of bacilli is found either in the flesh removed or in the patient's expectoration and yet the patient goes on to die of laryngeal tuberculosis, as the gradually increasing peribronchial and apical infiltration and consolidation, immediately following the surgical interference in the throat, indicated. Such a case is just now very distinct in my memory, and will recur to the mind of the distinguished physician who kindly recommended the case to me, but very unkindly, and I think unwisely, prevented my afterwards using tuberculin in the case, the only means I know of which would have compassed a cure, however incomplete that would have been. The prejudice in the minds of some of our best

physicians against even the advanced and enlightened use of tuberculin is as unreasonable as it is alarming. (2) An understanding of the absence of tubercle bacilli, or their tardy and very infrequent appearance, compared with the amount of glandular growth, in so-called scrofulous glands, with or without a coincident active tubercular process in some part of the body. (3) An understanding of the growth of tubercles, the "nodules" which have come down to us, previous to the discovery of the bacillus, as the essential feature of phthisis. As elsewhere explained in the essay on tuberculin, etc., previously referred to, I have myself a strong belief that these are the natural prison vaults built for the encapsulation of the tubercle bacilli, in which condition the germs, if not strangulated, are held so much in quiescence that they are incapable of propagation or further harm. This is a condition of arrest while it lasts, while the natural resistance of the system is maintained, which is perhaps about all nature can do in the direction of a cure. But the natural effort to maintain the integrity of the living cell is all the time active, and its mention here is made solely with the hope that some more worthy investigator will by its means, i. e., on natural grounds, elucidate for the medical profession the intricate problems here suggested.

---

#### PRACTICAL MEASURES IN THE PREVENTION OF TUBERCULOSIS.

By LAWRENCE F. FLICK, M. D., of Philadelphia, Pa.

The history of tuberculosis in all times and in all countries in which any history of it is recorded is a broad demonstration of its contagiousness and, by inference, of its preventability. So insidious, however, is its contagiousness, that although it has been recognized by the greatest minds of every age and has at times taken strong enough hold of the lay as well as of the medical mind to beget successful measures of prevention, at no time in the history of medicine prior to the present age had it been recognized and understood by the medical profession as a body. The contagious theory of tuberculosis is now so far accepted by the profession that it is being taught in our medical schools; so that the medical profession is committed to it at least through its teaching faculty. The prevention of the disease has, moreover, had sufficient practical testing to remove it from the category of experiments and place it upon the list of sanitary expedients deserving of the most earnest attention of sanitarians. Spain, by teaching its people the contagious nature of consumption and by practicing crude and unscientific but nevertheless successful methods of prevention, avoided carrying the disease into its new colonies in America; Italy, by similar methods, reduced the mortality rate from the disease in its midst from that of a most virulent epidemic to a comparatively rare disease in less than a century; England, by establishing special hospitals for the treatment of consumption and the consequent isolation of its consumptive poor, reduced its mortality 50 per cent in forty years; and Philadelphia, by preaching the doctrine of contagion and teaching its people methods of avoidance and prevention, has reduced the mortality rate from the disease about 20 per cent in eight years. With these facts before us, and with our profession committed to the theory of contagion, we can not, without failing in our duty, remain inactive while this disease carries off hundreds of thousands of human beings to a premature grave and inflicts indescribable suffering and loss upon hundreds of thousands of others. A comprehensive scheme for the prevention of tuberculosis implies: (1) Registration of all cases of the disease which have arrived at the breaking down or infectious stage; (2) the education of the public at large and of the people immediately concerned as to the contagious nature of the disease, and upon how to avoid contracting it, and how to avoid giving it to others; (3) the careful and thorough disinfection of all infected houses, penal and

reformatory institutions, conveyances, and public places; (4) the establishment of special hospitals for the treatment of the poor suffering from the disease; (5) the retirement of all consumptives in the infectious stage from occupations in which they can infect others and the pensioning of those who can not be maintained in hospitals; (6) Government inspection and regulation of dairies and slaughter-houses; (7) the enactment of laws and ordinances against practices which are liable to infect others; (8) the restriction and regulation of interstate and international emigration of persons suffering from the disease. The enforcement of such a scheme in every particular would completely wipe out tuberculosis in a very few years. Of this there can be no doubt, whether our conclusions be evolved from our present knowledge of the etiology of the disease or from what history records of the past attempts at prevention. As regards the respective merits of the measures named there will probably be a difference of opinion. I have enumerated them partly in the order of their importance as I rate them and partly in their natural order of sequence. The feasibility of their enforcement necessarily varies, and ought to determine which shall be adopted when all can not be adopted. At the present stage of sanitary science, and as Governments are now equipped for the prevention of disease, there is probably no country in which the entire scheme could be put into operation; nor is it likely that any Government is at present in a position to thoroughly enforce any of the measures. The prevention of tuberculosis is, however, so easily accomplished that even the incomplete enforcement of some of the measures would bring about a marked reduction in the mortality from the disease.

(1) *Registration of all cases which have arrived at the breaking-down or infectious stage.*—Registration is necessarily the foundation stone of all orderly, systematic effort at prevention. To be able to fight an enemy one must first know where he is. Even individual effort at self-protection is futile without it. Registration should not only record the residence, but also the movements of infectious persons, such as removals from one house to another or from one city to another; for a temporary residence in a house or even a transitory occupancy of a conveyance may infect it sufficiently to convey the disease to others. One consumptive, by frequent change of residence, may infect many houses during the continuance of the disease. Registration will be objected to on the ground that it will impose additional suffering upon those who are already sorely afflicted. In a matter of such great importance to the well-being of the majority of those now living and of all of those yet to be born, the greatest good to the largest number ought to be our motto. Moreover, the registration of infectious cases of tuberculosis need inflict no suffering on anyone that would not be fully compensated for by a knowledge that the near and dear ones can thereby be protected against the disease. Objections based upon commercial grounds have no foundation in fact. People are too familiar with consumption to take fright at it even when they believe it to be contagious. The registration of cases would have no depressing effect upon the community as a body, and whatever care-inspiring influence it might have upon individuals would be a benefit. Private business might, in certain cases, be injured because people would not buy at a place attended by a consumptive; but this would be a benefit to the community, and the individual concerned could easily rid himself of the injury by removing the attendant from a position in which he jeopardizes the health of others. Interference with the value of real estate would be prevented by Government disinfection of infected houses. As most countries are now equipped for carrying out sanitary measures registration would have to be accomplished through boards of health with the aid of practicing physicians. This is already being done with such diseases as smallpox, scarlet fever, typhoid fever, diphtheria, and some other contagious diseases. Many physicians object to being burdened with the labor of making out reports and to being

placed in the embarrassing position of having to make public the ailments of their patients. But with properly prepared blanks for the making out of reports it can be termed neither a labor nor a burden, and could easily be attended to by the busiest practitioner. As regards the making public the ailments of patients, it is under the circumstances not only a privileged communication, but one which the public has a right to insist shall be made. The physician has no reason to complain of such duties, because they belong to the profession which he has espoused. There can be no practical difficulty in the way of registering tuberculosis because of the obscurity of the disease or inability on the part of the physician to make a diagnosis. Tuberculosis is never contagious until broken tissue is given off, and when this occurs a diagnosis can always be positively made. There is no occasion for making a report until this stage has been reached.

(2) *The education of the public at large and of the people immediately concerned as to the contagious nature of the disease, and upon how to avoid contracting it, and how to avoid giving it to others.*—Of all contagious diseases the most easily prevented is tuberculosis. Its contagion is strictly confined to broken-down tissue, and this broken-down tissue, when given off, is readily recognizable—is indeed apt to attract attention. Efficient sterilization of all broken-down tissue must absolutely prevent the spread of the disease, and as this tissue is always within reach when it is a source of danger to others, and is never a source of danger to others unless it is within reach, sterilization is always feasible and is within the power of everyone. The proper education upon this subject of the public and the people who either have tuberculosis or are exposed to it would go a long way toward preventing the disease. The public at large ought to be educated upon the question of contagion. This can best be done through the public press, which has already accomplished a great deal in this direction. The people who have consumption ought to be taught how to avoid giving it to others, and the people who nurse consumptives or whose duties require them to be about those who have the disease should be taught how to avoid contracting it. Special literature ought to be prepared for such persons and placed within their reach. This can be accomplished through boards of health, and better still through the organized efforts of humane persons who have given the subject special thought. Societies for the prevention of tuberculosis will find in this work not only a legitimate cause for springing into existence, but a field of labor worthy of their most earnest efforts. Such societies ought to be organized everywhere, and a concerted effort should be made the world over to educate the people on methods of avoidance and prevention. The Pennsylvania Society for the Prevention of Tuberculosis was organized in Philadelphia about two years ago, and during its brief existence has printed and distributed about 30,000 tracts on *How to Avoid Contracting Tuberculosis and How Persons Suffering from Tuberculosis can Avoid Giving the Disease to Others*. There is reason to believe that its efforts are already bearing good fruit in an increased reduction in the mortality rate from the disease in Philadelphia. The greatest obstacle in the way of performing its work has been non-registration of the disease. Were every case of tuberculosis registered it would be an easy matter to place literature where it would do the most good.

(3) *The careful and thorough disinfection of all infected houses, penal and reformatory institutions, conveyances, and public places.*—Were it possible to induce every person suffering from tuberculosis to sterilize every particle of broken-down tubercular tissue immediately upon its being given off it would not be necessary to institute any other measures for the prevention of the disease. Unfortunately, it is not possible. The majority of consumptives, even when they have been informed of the infectious character of the sputa, will spit where it is most convenient, and thus contaminate everything about them. Infected houses play a most important rôle in the spread of the disease. In my topographical study of tuberculosis in the

Fifth ward of the city of Philadelphia I found that at least 50 per cent of all cases were contracted in such houses. Dr. Chapin, of Springfield, Mass., and Dr. Louis S. De Forrest, of New Haven, Conn., have since made similar studies in their respective towns with identically the same results. Dr. Cornet, of Berlin, has produced tuberculosis in animals by inoculating them with the scrapings from walls of rooms which had been occupied by consumptives. Penal and reformatory institutions have been so scourged by tuberculosis that commitment to them is frequently tantamount to a death sentence. In Germany, Baer and Cornet have made statistical studies of this subject, and have found that from 45 to 70 per cent of all deaths in penal institutions are due to tuberculosis. Conveyances, such as steamboats, railway cars, street cars, carriages, etc., and public places, such as churches, public halls, public squares, and streets, are constantly being contaminated with the expectorations of consumptives. Fortunately, however, they are not prolific sources of infection, because most people require prolonged and continuous exposure to contract tuberculosis. But persons who are greatly predisposed to the disease or who are in a weakened, depressed condition will contract the disease upon slight exposure and to such, infected conveyances and public places are a real source of danger. With the clear knowledge that we have upon these various methods of spreading the disease it is incumbent on the Government to see that every place which has become contaminated with broken-down tubercular tissue be carefully disinfected. When a death from tuberculosis has occurred in a house the board of health should see that the rooms occupied by the deceased and the furniture and clothing which could in any way have been contaminated be properly disinfected. When a house has been disinfected it should be so recorded in an open record of easy access to the public, so that persons seeking residences can first inform themselves as to whether or not a house is free from contagion. In penal and reformatory institutions every cell or room which has been occupied by a consumptive should be thoroughly disinfected before being assigned to a new occupant. Here the authorities have absolute power, and there ought to be no difficulty about enforcing the most rigid rules in regard to prevention and securing the most thorough disinfection after contamination. The disinfection of conveyances and public places will have to be left largely to the sense of justice and propriety of those who have charge of them, as it is practically impossible to make and enforce rules covering such cases. Much can, no doubt, be accomplished by education. Most people are well disposed to do what they can to prevent the spread of disease, provided they have the proper knowledge and the necessary means. The demands of an enlightened public will probably be the most powerful lever that can be brought to play upon both individuals and corporations who have charge of any and all kinds of conveyances and places of public resort to induce them to keep them free from contagion.

(4) *The establishment of special hospitals for the treatment of those suffering from the disease.*—Among the very poor, preventive measures in their homes are so difficult of execution that they are practically impossible. Families who can barely make a living during health, and of which every member has to contribute toward a common fund for sustenance, are so badly upset by a prolonged illness such as tuberculosis that they are not capable of either understanding or putting into operation any systematic sanitary measure. Everything is made subservient to the happiness, comfort, and freedom from worry of the sick one. The room that serves as the family kitchen and dining room is turned into a sick room, and spitting all over it, into the coal scuttle or into the front of the cooking stove, anywhere, indeed, that is convenient, is a privilege that is freely accorded. Such habits in such places mean extension of the disease to the weakest member of the family until, in turn, everyone has taken on the rôle of victim and propagator of the disease. Among this class of people the most efficient measure for

the prevention of the disease is the establishment of special hospitals for the treatment of those who are stricken down. Removal of the patient to a hospital removes the source of infection and at the same time relieves the pressure of worry, want, and care which is so strongly predisposing the remaining members of the family for the disease. Special hospitals for the treatment of tuberculosis have existed in Europe, and especially in England, for many years. In England the motive for their establishment was not prevention, but extending charity to the deserving poor. Now that it has been demonstrated that segregation will prevent the disease, and we still have the inspiring motive that England had, we ought to move more rapidly in the matter than is possible on the slow wheels of charity. While every effort to establish special hospitals on the basis of charitable support should be encouraged by generous aid, the Government should promptly establish such hospitals on its own account. The only legitimate ground upon which the Government can appropriate money for the support of hospitals is that of protecting the public against disease and death. In as much as tuberculosis has been demonstrated to be a preventable disease, and it has been proven by experience that segregation will prevent it, the establishment of consumption hospitals becomes as much a Government function as the maintenance of a police force. The truth of this proposition must sooner or later force itself upon every enlightened Government. In considering the matter of special hospitals for the treatment of tuberculosis as a preventive measure the question of forcible segregation, with its horrible features, need not have any deterring influence. In the first place, there is no necessity for it. Were hospital doors thrown open for such cases there would be more applicants for admission than could be accommodated. With all its present capacity, which is very large indeed, England can not accommodate the poor consumptives who appeal for admission into its special hospitals. In the next place, an alternative can always be given without jeopardizing public health. In a given case of tuberculosis in which the question of forcible segregation might come up, the sick person and the family could be given a choice to either have the patient go to a hospital or practice certain preventive measures at home. Such measures could then be enforced by the board of health, as there would be a penalty at hand to support the order. In our American system of government the taxation for the support of such hospitals ought to be as direct as possible, and for this reason they ought to be established and maintained largely by cities and States. Every large city should have such hospitals under the supervision and support of the city government, and every State should have at least one such hospital under its supervision. It would be a step in the right direction of judicious bestowal of charity if some of the general hospitals of our large cities would take up this subject and devote themselves entirely to the care of the consumptive poor. It is a well-known fact that the unfortunate victims of this disease are turned away from general hospitals because of the disease from which they suffer. As general hospitals have grown so numerous of late that there is at times a lively competition for patients, it would no doubt prove a wise deviation from the beaten path for some of them to take up this specialty.

(5) *Government inspection and regulation of dairies and slaughter-houses.*—Ever since it became known that tuberculosis affects animals as well as man, and that it is identically the same disease in both, there has been much speculation as to which was attacked first, and what part they respectively play in infecting each other. Some who have given the subject much thought and study, and notably among them Dr. E. F. Brush, of Mount Vernon, N. Y., claim that the disease is primarily a bovine disease, and that human beings and animals other than the cow are infected from this source. I have myself never been able to accept this theory, but whether we accept it or not so much is certain that human beings and domestic animals can and constantly are infecting each other. The mediums

through which the cow infects human beings are milk and meat. Much study has been given to this subject both in this country and in Europe, and we now have a pretty clear idea as to what constitutes infectious milk and meat. The milk of a tuberculous cow is not apt to be infectious unless the udders are diseased so that the secretion becomes mixed with broken-down tubercular tissue. At all events it is necessary that the bacilli gain entrance into the milk to make it capable of conveying the disease. The meat of a tuberculous animal is only infectious when the deposit exists in the parts that are consumed or when those parts have become contaminated in slaughtering and preparing for the market. It is important that these facts be kept clearly in mind because of the important positions which meat and milk occupy as food stuffs, and the great injury that can be done by exaggerating the danger from using them. Clinically we have very little evidence of the conveyance of the disease through these mediums. I have never seen an authenticated case recorded in literature, and personally I have never seen a case which I could trace to the use of meat, and have seen but a few cases in which there was satisfactory evidence that they were contracted from the use of milk. But while scientific investigations and clinical observations both point to the conclusion that in practical life the use of milk and meat are not prolific sources of infection of tuberculosis it nevertheless can not be denied that they are sources of sufficient importance to demand the most earnest attention of the Government. An effort should be made to stamp out tuberculosis among cattle. To accomplish this the coöperation of Federal, State, and city governments will be needed. The Federal Government should prohibit and prevent the importation of tuberculous cattle. State governments should carefully examine every herd within their borders, and condemn every head that is in the slightest degree affected by the disease. Cities should condemn and forbid the sale of every carcass that shows the slightest evidence of taint in the slaughter-house, and permit no one to sell milk within its limits except such as draw their supply from dairies of which the herds have been officially examined. Such concerted effort would soon stamp out the disease among cattle, for it would no longer be commercially profitable to keep anything but healthy herds. Actual loss to individuals ought, of course, to be made good by the Government.

(6) *The enactment of laws and ordinances against practices which are liable to infect others.*--Civilized man, in spite of his civilization, retains many of his primitive habits. Among these is the horrible custom of spitting anywhere and everywhere that is convenient. There are a great many diseases the contagion of which resides in expectoration, all of which put people to a great deal of inconvenience, but none of which are so serious in their results as tuberculosis. How much would be added to the comfort and happiness of the human family were it possible to put a stop to this filthy custom. The promulgation of knowledge about the danger of promiscuous spitting would no doubt contribute something toward breaking up the custom. It is, however, so much easier and more convenient to spit out than into a cuspidor or handkerchief, that with the majority of people it will require more than education to induce them to change their habits in this regard. The necessity of washing handkerchiefs no doubt contributes something toward the custom and its continuance after people know the danger. The introduction of cheap paper handkerchiefs which could be burned after using would do away with this excuse for the habit. The enactment of State laws and city and borough ordinances against spitting in public conveyances, in public places, or upon the streets would, however, be the most powerful lever that could be brought to bear upon the custom with the masses. It would be difficult to enforce such laws and ordinances, and they probably could not be enforced to the letter. Their existence and attempted enforcement would, however, do much good, even as a means of education. Many street-car companies now have notices up in the cars warn-

ing passengers not to spit upon the floor, but they do not attempt to enforce the order, probably because they have no warrant of law to support them should the matter be brought to an issue. The disposal of clothing and furniture either by gift or sale without previous disinfection is another practice fraught with great danger. The Spaniards and Italians recognized this source of infection a century ago, and took the most careful precautions against it. Their method was cumbersome and would not do as a model, but it was effective, and serves to illustrate what can be accomplished by a determined effort. The simplest way of stopping this mode of spreading the disease would be to make it a misdemeanor to dispose of anything, whether by sale or gift, that had been used by a consumptive or had been in his room during his occupancy, without first thoroughly disinfecting it. Here again would of course come up the difficulty of enforcing the law, but the existence of such a law would at least enable individuals to protect themselves.
